Diagnostic whole-cell sugars are galactose, mannose, xylose and rhamnose as well as small amounts of ribose and arabinose (sugar pattern is D). Major fatty acids are $C_{17:0}$ anteiso (30.0–38.0%), $C_{15:0}$ anteiso (12.5–14.0%), $C_{16:0}$ iso (10.0–15.0%) and $C_{15:0}$ iso (10.1–12.0%) (fatty acid type 2d).

Phylogenetic analysis of the 16S rRNA gene positions the genus within the family *Micromonosporaceae*. The closest phylogenetic neighbor is *Micromonospora pattaloongensis* (96.7% sequence similarity) (Thawai et al., 2008). An environmental clone with high 16S rRNA gene sequence similarity has been detected in undisturbed tallgrass prairie soil in central Oklahoma (97.3%, accession no. FJ479324; Youssef et al., 2009).

Enrichment and isolation procedures

Strains 3-9(24)[T], 3-21(27) and 7-40(26)[T] were isolated from sandy soil collected in Chokoria and Cox's Bazar, Bangladesh. Serial diluents of the soil were transferred onto humic acid-vitamin agar (HV) (Hayakawa and Nonomura, 1987a) supplemented (per liter) with 50 mg cycloheximide, 50 mg nystatin and 20 mg nalidixic acid. Plates were incubated for 21 d at 30°C, then strains were transferred and purified on ISP medium 2 (yeast extract-malt extract agar, medium 2 of the International *Streptomyces* Project) (Shirling and Gottlieb, 1966).

Maintenance procedures

Working cultures are maintained on JCM medium 61 (per liter: 15.0 g soluble starch, 4.0 g yeast extract, 0.5 g K_2HPO_4, 0.5 g $MgSO_4 \cdot 7H_2O$, and 15.0 g agar; pH 7.2).

Differentiation of the genus *Luedemannella* from closely related genera

Possession of major menaquinones MK-9(H_6) and MK-9(H_4) as well small amounts of MK-9(H_2) and MK-9(H_8) distinguishes *Luedemannella* is from other phylogenetically related genera, which possess a variety of different menaquinone profiles: *Longispora*, MK-10(H_4) and MK-10(H_6); *Micromonospora*, MK-10(H_4), MK-10(H_6), MK-9(H_4) and MK-9(H_6); *Salinispora*, MK-9(H_4); *Actinocatenispora*, MK-9(H_4) and MK-9(H_6); *Polymorphospora*, MK-10(H_6), MK-10(H_4), MK-9(H_6) and MK-9(H_4); *Actinoplanes*,

MK-9(H_4) and MK-10(H_4); *Asanoa*, MK-10(H_6) and MK-10(H_8); *Catellatospora*, MK-9(H_4) and MK-9(H_6) or MK-10(H_4) and MK-10(H_6); *Catenuloplanes*, MK-9(H_8) and MK-10(H_8); *Couchioplanes*, MK-9(H_4); *Dactylosporangium*, MK-9(H_4), MK-9(H_6), and MK-9(H_8); *Pilimelia*, MK-9(H_4) and MK-9(H_2); *Spirilliplanes*, MK-10(H_4); *Verrucosispora*, MK-9(H_4); *Virgisporangium*, MK-10(H_4), MK-10(H_6), and MK-10(H_8); *Plantactinospora*, MK-10(H_6), MK-10(H_8), and MK-10(H_4); *Planosporangium*, MK-9(H_4) and MK-10(H_4); *Pseudosporangium*, MK-9(H_6). *Luedemannella* is also differentiated from other genera within the family by the presence of diagnostic whole-cell sugars including galactose, mannose, xylose and rhamnose along with small amounts of ribose and arabinose. *Luedemannella* possess all family-specific nucleotide signatures of 16S rRNA gene, except for the "U–A" pair at position 139:224, "A" at position 381, the "A/G–C" pair at position 656:750 and the C–U pair at position 999:1041.

List of species of the genus *Luedemannella*

1. **Luedemannella helvata** Ara and Kudo 2007c, 1372[VP]

hel.va′ta. N.L. fem. adj. *helvata* honey yellow, referring to the color of the substrate mycelium.

Vegetative mycelia are shell to melon yellow in color and aerial mycelia are not present. D-glucose, L-arabinose, maltose, and trehalose are utilized. D-Xylose, lactose, sucrose and D-raffinose are moderately utilized; erythritol, D-galactose and salicin are poorly utilized. Growth is not affected by glycerol, adonitol, D-ribose, D-fructose, D-mannose, L-rhamnose, *myo*-inositol, D-mannitol, α-methyl-D-glucoside, and α-D-melibiose. Temperature range for growth is 20–37°C, pH range is 5–9, NaCl tolerance is <3%. Grows well on yeast-extract-malt extract agar, Bennett agar, and glucose yeast extract agar. Moderate growth on ISP media 4 and 3, Hickey–Tresner agar, sucrose-nitrate agar, yeast extract-starch agar (JCM medium 61), oatmeal-nitrate agar, 1/5 yeast extract-starch agar (JCM medium 202), sucrose-beef extract agar, ISP medium 1, and 1/20 V8 juice agar. Melanin pigment production on ISP medium 7 is negative. Abundant sporulation occurs on nutrient agar, sucrose-nitrate agar, yeast extract-starch agar, 1/5 yeast extract-starch agar, and 1/20 V8 juice agar, and moderate sporulation occurs on glucose-asparagine agar, glycerol-asparagine agar, tyrosine agar, yeast extract-malt extract agar, oatmeal agar, Bennett agar, glucose-yeast extract agar, Hickey–Tresner agar, tap water agar, and oatmeal-nitrate agar.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 71 (HPLC).

Type strain: 3-9(24), JCM 13249, MTCC 8091.

Sequence accession no. (16S rRNA gene): AB236957.

2. **Luedemannella flava** Ara and Kudo 2007c, 1372[VP]

fla′va. L. fem. adj. *flava* yellow, referring to the color of the substrate mycelium.

Vegetative mycelia are cream yellow to wheat yellow in color and aerial mycelia are not present. D-glucose, L-arabinose, maltose, trehalose, D-xylose, D-galactose, D-mannose, L-rhamnose, salicin, lactose, α-D-melibiose, and sucrose are utilized. Glycerol, D-ribose, D-fructose, *myo*-inositol, D-mannitol, and α-methyl-D-glucoside are poorly utilized. Growth is not affected by erythritol, adonitol, and D-raffinose. Temperature range for growth 20–30°C, pH range 6–9, NaCl tolerance <2%. Grows well on oatmeal agar (ISP medium 3), Bennett agar, glucose-yeast extract agar, Hickey–Tresner agar, yeast extract-starch agar (JCM medium 61) and 1/5 yeast extract-starch agar (JCM medium 202). Moderate growth on yeast extract-malt extract agar and oatmeal-nitrate agar. Melanin pigment production on ISP medium 7 is negative. Abundant sporulation occurs on glucose-asparagine agar, ISP media 5 and 4, tap water agar, and 1/5 yeast extract-starch agar; moderate sporulation on ISP medium 7, glucose-yeast extract agar, Hickey–Tresner agar, sucrose-nitrate agar, and oatmeal-nitrate agar; and no sporulation on nutrient agar, yeast extract-malt extract agar, ISP medium 3, Bennett agar, or yeast extract-starch agar.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 71 (HPLC).

Type strain: 7-40(26), JCM 13250, MTCC 8095.

Sequence accession no. (16S rRNA gene): AB236959.

Genus XII. **Pilimelia** Kane 1966, 225[AL]

Gernot Vobis and Peter Kämpfer

Pi.li.mel′i.a. L. n. *pilus* a hair; Gr. fem. n. *melia* Melia, a nymph loved by the river god Inachus; N.L. fem. n. *Pilimelia* an aquatic organism growing on hair substrate.

Members of the genus produce substrate mycelium. Hyphae are Gram-stain-positive, 0.2–0.8 µm in diameter, branched, and septate. True aerial mycelium is not developed. **Sporangia** are produced **on the surface of the substrate** on sporangiophores. The shape of sporangia is **spherical, ovoid, pyriform, campanulate, or cylindrical**, approximately 10–15 µm in size. Sporangia contain **numerous spores in chains** that are arranged in parallel or irregularly in swirl-like rows. **Spores (zoospores)** are **rod-shaped** (0.4 × 1.2 µm) and **motile** by means of a **laterally inserted tuft of flagella**. Nonmotile spores develop in free chains arranged similarly to the zoospores. Colonies grow only on complex media and are small, compact, soft, pasty, or

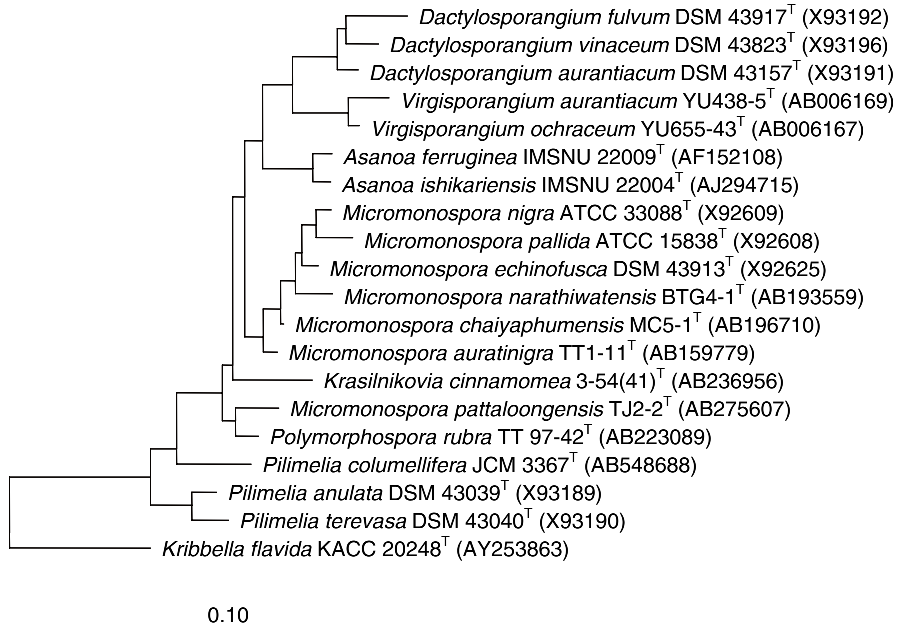

FIGURE 222. Phylogenetic tree showing the relationship of type strains of the genus *Pilimelia* and the related genus *Dactylosporangium*. The tree was reconstructed using the maximum-likelihood method using the software environment ARB (Ludwig et al., 2004) and the corresponding SILVA SSURef 95 database (release July 2008; Pruesse et al., 2007). Bar = 0.10 substitutions per site.

solid. **Color of substrate mycelium is pale lemon-yellow, golden yellow, orange, or pale**, turning brown to dark with age. Aerobic and chemo-organotrophic. Optimal growth is at pH 6.5–7.5 and 20–30°C (minimum 10°C, maximum 38°C). **Strains decompose keratinic substances** (e.g. hair of mammals). The peptidoglycan of the cell walls contains ***meso*-diaminopimelic acid** (*meso*-**DAP)** and **glycine**, with **xylose** and **arabinose** as characteristic sugars of whole-cell hydrolysates.

DNA G+C content (mol%): 71 (Miyadoh et al., 2001).

Type species: **Pilimelia terevesa** Kane 1966, 225^{AL}.

Further descriptive information

Phylogeny. On the basis of 16S rRNA gene sequence analysis, the genus *Pilimelia* belongs to the family *Micromonosporaceae* and contains three species and two subspecies with validly published names. *Pilimelia* species form a distinct phylogenetic cluster within the family *Micromonosporaceae* although the genus does not appear to be monophyletic. The 16S rRNA gene sequence similarity between the three species is between 96.1 and 98.6%. Similarity values of *Pilimelia columellifera* subsp. *columellifera*, *Pilimelia anulata*, and *Pilimelia terevasa* and type strains of the closely related genera are 94.1–96.85% for *Micromonospora*, 96.2–96.7% for *Polymorphospora*, 95.5–96.0% for *Krasilnikovia*, and 95.5–96.0% for *Asanoa*. Interestingly, *Pilimelia columellifera* subsp. *columellifera* JCM 3367^{T} shares a similarity value of 97.8% with *Micromonospora pattaloongensis* TJ2-2^{T}; however, chemotaxonomic and other phenotypic data indicate that this strain does not belong to the genus *Micromonospora*. A phylogenetic tree is shown in Figure 222. At present, no sequence is available for the type strain of *Pilimelia columellifera* subsp. *pallida*.

Cell morphology. The fine structure of the walls of hyphae and spores of *Pilimelia* is typical for those of Gram-stain-positive cells. A single compact layer surrounds the cytoplasm, which contains irregularly elongated nucleoid regions, ribosomes, and vacuole-like structures. Mesosomes are connected to the nuclear material or involved in the formation of cross-walls (Bland, 1968; Vobis, 1984). The cross-walls of substrate hyphae have the typical solid structure of Gram-stain-positive bacteria (cross-wall "type 1" of Williams et al., 1973). Typical interspace or "split" septa are observable in sporangial development (Vobis, 1984; Vobis et al., 1986b). Hyphae in contact with the air are additionally covered either by a thin sheath or by a thick layer of perhaps fibrous and mucilaginous material. The sporangial envelopes originate from these outer layers (Bland, 1968; Vobis, 1984).

The sporangia have different shapes and sizes and each species can be characterized by a special morphological type of sporangia (Figure 223; Table 200). Typical cylindrical sporangia are produced by *Pilimelia anulata*, reaching lengths of 10–35 µm (Kane, 1966); *Pilimelia columellifera* has spherical or oval to pyriform sporangia with diameters of 7–15 µm (Vobis et al., 1986b). Globose sporangia are also developed by *Pilimelia terevasa*, their size ranging between 5 and 23 µm (Kane Hanton, 1974). Other strains of *Pilimelia* have campanulate, inverse conical, heart-shaped, or flabelliform sporangia (Figure 223E) (Gaertner, 1955; Karling, 1954; Rothwell, 1957; Vobis et al., 1986b). Presumably, they belong to *Pilimelia terevasa*. After repeated subculturing, the strains may lose the ability to produce sporangia (Kane Hanton, 1974). The polysporous sporangia are developed at the tip of thickened hyphae that penetrate the surface of the substrate. These hyphae may be called palisade hyphae (Bland, 1968) or sporangiophores (Vobis, 1997). When sporangia are mature, the cytoplasm of the sporangiophores is

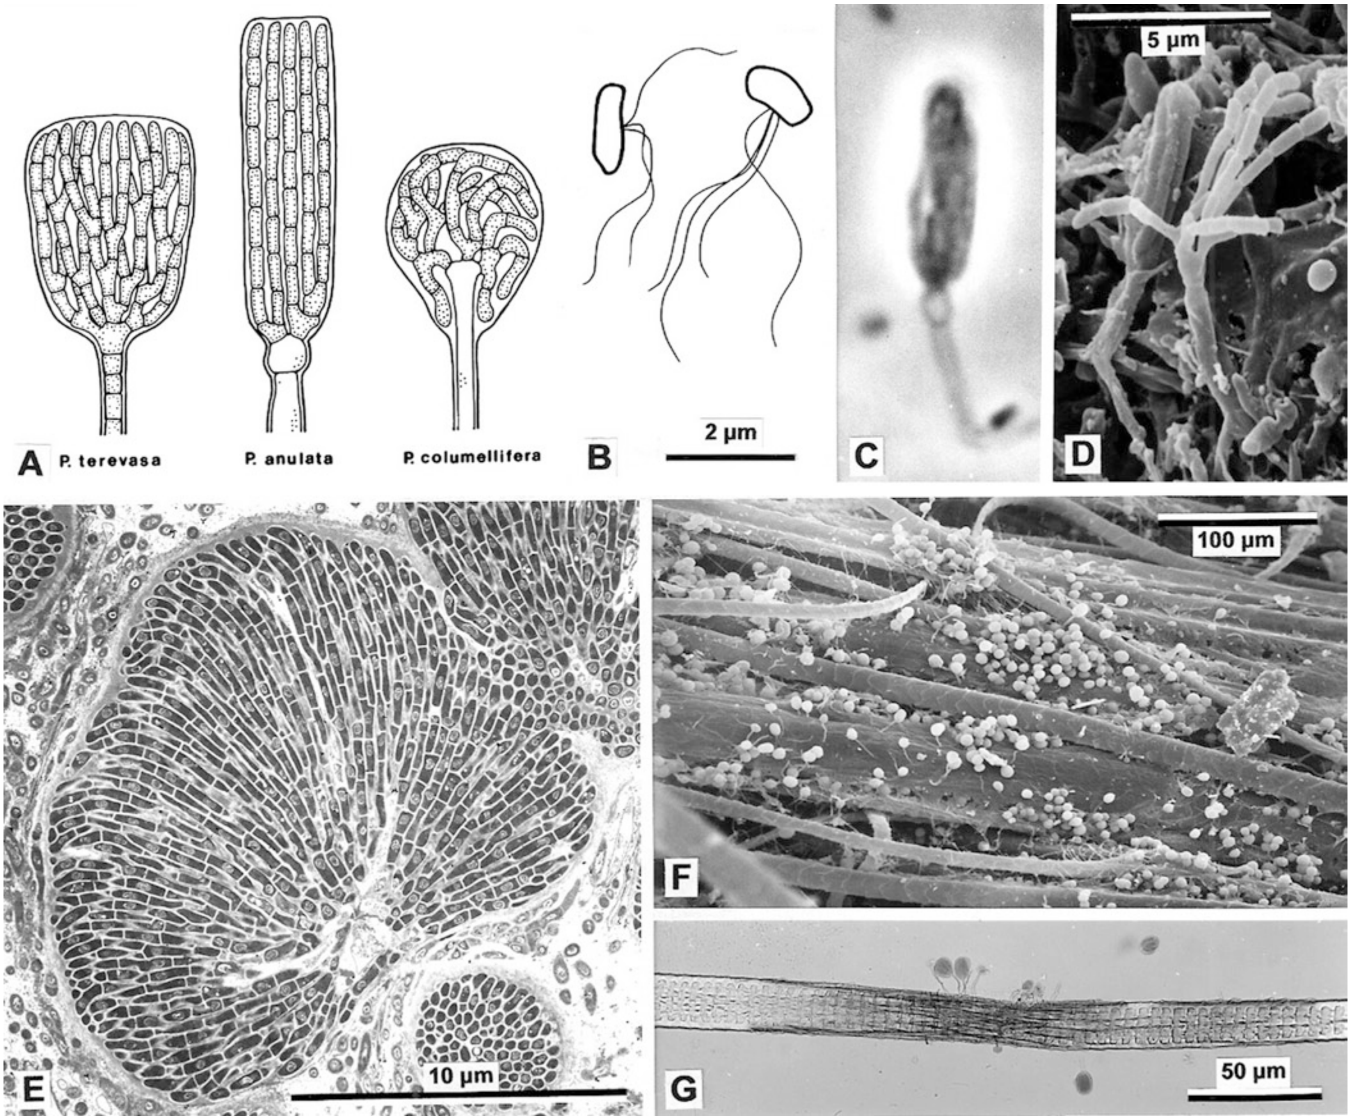

FIGURE 223. Morphological aspects of *Pilimelia*. A, Scheme of the different types of sporangia; B, rod-like sporangiosphores with laterally inserted tuft of flagella; C, cylindrical sporangium of *Pilimelia anulata* ATCC 25604^{T} with a basal ring-like structure (PHACO, magnification as in D); D, conidiophore of *Pilimelia anulata* ATCC 25604^{T} bearing chains of conidia (SEM); E, transverse section of a flabellate sporangium of strain MB-VK 122 with branched parallel rows of spores (TEM); F, globose sporangia on the surface of a colony of *Pilimelia columellifera* strain MB-SK6 cultivated on artificial soil agar and hair of white mice (SEM); G, hair colonized by a strain of *Pilimelia*, attacked section is darkly stained with cotton blue (LM). Abbreviations: LM, light microscopy; PHACO, phase contrast microscopy; SEM, scanning electron microscopy; TEM, transmission electron microscopy.

generally autolyzed. The different morphological characters of the sporangiophores are of diagnostic value (Table 200). In *Pilimelia terevasa* and *Pilimelia anulata*, they are fragmented by double-layered cross-walls (Vobis et al., 1986b). The uppermost fragment can be swollen to a ring-like structure or annulus, the distinctive structure of *Pilimelia anulata* (Figure 223C). In *Pilimelia columellifera*, the sporangiophores are not septate, but extend into the lumen of the sporangia to form clearly visible, nail-shaped columellae (Schäfer, 1973). The sporangiophores are arranged in either branched parallel (*Pilimelia terevasa* and *Pilimelia anulata*) or swirl-like (*Pilimelia columellifera*) rows (Figure 223A). It is estimated that one sporangium can contain from hundreds to several thousand spores (Vobis, 1984). The ultrastructure of sporangial development was described by Vobis (1984), confirming the scheme of sporangium formation as proposed by Lechevalier and Holbert (1965) for sporangiate actinomycetes.

The shape of the zoospores released from sporangia is rod-like. Occasional variations of slightly curved or reniform spores originate from branching segments of the sporogenous hyphae (Figure 223A, E). The spores can vary from 0.3 to 0.7 µm in diameter and 0.7 to 1.5 µm in length, and bear a laterally inserted tuft of flagella (Figure 223B) (Vobis et al., 1986b). A single flagellum might reach 5 µm in length with a diameter of about 11 nm. The flagella are frequently bundled and may function as a unit (Schäfer, 1973; Vobis, 1984).

Pale	−	−	+

[a]Symbols: +, >85% positive; −, 0–15% positive.

Nonmotile spores (conidia) may be produced (Figure 223D), mainly in the aqueous milieu of the substrate (Kane, 1966). The conidia develop in chains that are arranged in a pattern similar to the spore chains inside the corresponding sporangia (Kane, 1966; Schäfer, 1973; Vobis and Kothe, 1985). The formation of these unflagellated spores may be a variation of sporangial development in which the sporangial envelope is not formed (Gaertner, 1955).

Cell-wall composition. The peptidoglycan of the cell wall contains *meso*-DAP and glycine according to chemotype II of Lechevalier and Lechevalier (1970a), with xylose and arabinose as characteristic sugars in whole-cell hydrolysates (sugar pattern D) (Szaniszlo and Gooder, 1967; Vobis et al., 1986b). The acyl groups of the muramyl residues of the cell-wall peptidoglycans are of the glycolyl type, exhibiting high amounts of glycolic acid with 149 nmol/mg of cells for *Pilimelia anulata*, 141 nmol/mg for *Pilimelia terevasa*, and 74.0 nmol/mg for *Pilimelia columellifera* subsp. *columellifera* (Uchida and Seino, 1997).

The polar lipid profile is characterized by the presence of phosphatidylethanolamine and phosphatidylcholine and the absence of the unknown glucosamine-containing phospholipid (Vobis et al., 1986b). The phospholipid type of the cell membrane corresponds to type II of Lechevalier et al. (1981).

Fatty acids. *Pilimelia* strains have a high content (>50%) of C_{15} iso, $C_{15:1}$ iso, and $C_{17:1}$ fatty acids, and lack substantial amounts of C_{18} fatty acids (Stackebrandt and Kroppenstedt, 1987). The fatty acid pattern corresponds to type 2b of Kroppenstedt (1985).

The menaquinone composition in *Pilimelia* is predominantly MK-9(H_2) and MK-9(H_4), thus fitting into type 4a of the classification scheme of Kroppenstedt (1985).

Colonial characteristics. *Pilimelia* strains grow very slowly. Small colonies of about 5 mm in diameter develop after 4–6 weeks of incubation. These are compact and grow only with substrate mycelium, aerial mycelium is not produced. *Pilimelia terevasa* and *Pilimelia anulata* have soft and pasty colonies, colored bright lemon-yellow to yellow-gray. In both species, intra-mycelial pigments have been reported. The properties of absorption spectra are associated with carotenoids, with peaks at 479, 451, and 425 nm with an absorption maximum at 451 nm (Szaniszlo, 1968). In comparison with the spectral properties of extracts of *Actinoplanes* strains, the absorption peaks are shifted about 22 nm toward the UV region, indicating that the conjugated double bond system of the carotenoids of *Pilimelia terevasa* and *Pilimelia anulata* has one double bond less than that of *Actinoplanes* species (Parenti and Coronelli, 1979). The colonies of *Pilimelia columellifera* are solid and hard, either golden yellow to orange (subsp. *columellifera*) or pale (subsp. *pallida*) (Table 200). Growth occurs only on complex media such as 50% diluted skim milk agar (Gordon and Smith, 1955), Casamino acids-peptone Czapek agar (Henssen and Schäfer, 1971), nutrient-sugar agar (Henssen and Schäfer, 1971), peptone-yeast extract-iron agar (Shirling and Gottlieb, 1966), oatmeal-yeast extract agar (Vobis et al., 1986b), and yeast extract-starch agar (Emerson, 1958). On these nutrient-rich media, the colonies do not penetrate deeply into the agar but grow upward. Sporangial development rarely occurs. Nutrient-poor media with addition of natural keratinic substances promote the production of sporangia. Good examples are the artificial soil extract agar of Henssen and Schäfer (1971) combined with hair of white mice (Figure 223F), or highly diluted skim milk-mineral agar with the addition of cattle horn meal (Schäfer, 1973; Vobis, 1984, 1992). On these media, the colonies are more flat and the substrate hyphae penetrate deeply into the agar. The skim milk-cattle horn meal agar is highly recommended for starting a new culture (Vobis, 1992).

Life cycle. Sporangia with thick envelopes may function as a resistant form surviving in soil or disseminated as diaspores, possibly attached to soil particles and distributed by actively moving members of the edaphon like nematodes and arthropods. Transport over long distances by the wind is also easily imaginable. If sporangia are dipped into water, numerous flagellated spores are released, leaving behind the sporangial envelope (Vobis, 1984). The zoospores are also adapted to disseminate in water. If sporangia of *Pilimelia columellifera* are flooded with distilled water, motile spores are released after 45–60 min (Vobis et al., 1986b). The spores seem to swim randomly (Vobis, 1984). The laterally inserted tuft of flagella functions as a propelling flagellum and pushes the rod-shaped spore forwards. In microscopic water preparations, this type of movement in one direction, perpendicularly orientated to the longitudinal axis of the spore, is only hardly noticeable. Additionally, the spore moves like a slowly rotating screw. In addition to single spores, short chains of two or three spores can also be observed swimming actively in water (Vobis, 1984). On reaching natural keratinic substances, e.g. hair of mammals, they colonize the new substrate to produce mycelium and sporangia within 14 d (Vobis, 1989a). The life cycle of *Pilimelia* can be considered as "aero-aquatic" (Vobis, 1987), typical for all ecologically defined "actinoplanetes" (Makkar and Cross, 1982; Nonomura and Takagi, 1977).

TABLE 201. Other characteristics of species and subspecies of the genus *Pilimelia*[a,b]

Characteristic	*P. terevasa*	*P. anulata*	*P. columellifera* subsp. *columellifera*	*P. columellifera* subsp. *pallida*

[b]Data from studies of type strains (Vobis et al., 1986b).

[c]Data compiled from Kane Hanton (1974), Schäfer (1973), and Vobis et al. (1986b).

Metabolism and physiology. Members of the genus *Pilimelia* are aerobic and mesophilic with growth optima between 20 and 30°C, although exceptional growth has been observed at 42°C (Schäfer, 1973). The pH range of growth is restricted to between 5.0 and 7.8. Colonies grow well at about pH 7.0. For more details and other physiological properties see Table 201. *Pilimelia* strains utilize neither the various carbon sources recommended by Shirling and Gottlieb (1966) (Vobis et al., 1986b) nor individual or combinations of purified amino acids as a sole source of nutrition (Kane Hanton, 1974). Four *Pilimelia* strains isolated from rhizosphere of the actinorhizal plant *Ochetophila* (= *Discaria*) *trinervis* did not show any enzymic activity to decompose substrates of vegetable origin like starch, cellulose, hemicellulose, pectin, or lignin (Solans and Vobis, 2003). The capacity to degrade natural keratinic substances, which can be observed easily by microscopic preparations of infected hairs, is highly conspicuous (Figure 223G). Further physiological investigations are needed to understand the high specialized enzymic activity of *Pilimelia*.

Ecology. Strains of *Pilimelia* must have a worldwide distribution (see also species descriptions). The discoverer of these rare actinomycetes, Karling (1954), first detected them in baited soil cultures from New York City, USA, in 1938 and later in soil samples from various parts of the Amazon Valley in Brazil, as well as from New Jersey, Virginia, Louisiana, Indiana, and Iowa (USA). Schäfer (1973) registered a total of 96 out of 427 soil samples, collected from different geographical regions of the world (22%), that produced of *Pilimelia* sporangia in enrichment cultures. Gaertner (1955) confirmed that 16% of his soil samples from the African continent were positive for the presence of *Pilimelia*. Strains presumptively identified as *Pilimelia terevasa* and *Pilimelia columellifera* have been reported to be widely distributed in diverse soils from England (Tribe and Abu El-Souod, 1979).

The investigations of Garrity et al. (1996) demonstrated that in the arid environment of the Mojave Desert along the California–Nevada border, 34 *Pilimelia*-like isolates could be recovered from eight out of 32 soil samples using the baiting technique. The total number of isolates was estimated as low, but the overall diversity was high. Accordingly, organisms belonging to *Pilimelia* do not occur so rarely in nature, but they are very difficult to isolate and cultivate (Schäfer, 1973; Vobis et al., 1986b).

Pilimelia strains are remarkable "nutrition specialists". In baiting experiments, they colonize and decompose natural keratinic material like hair of cows, horses, mice, rats, dogs, and deer (Gaertner, 1955; Makkar and Cross, 1982; Schäfer, 1973), and human hair (Kane, 1966; Rothwell, 1957). Infected parts of the hair lose their stability and external structure (Vobis, 1984). In addition to the degradation of mammalian hair, feathers of birds or snake skin can also be colonized and attacked by *Pilimelia* strains (Karling, 1954; Schäfer, 1973). These unusual keratinophilic micro-organisms may occupy an important ecological role in soil by decomposing the recalcitrant scleroproteins of vertebrates, especially hair of mammals (Gaertner, 1955). They have not yet been found to be dermatophytes.

Enrichment and isolation procedures

Strains of *Pilimelia* can be baited with natural keratinic substrates (Bland and Couch, 1981; Kane, 1966; Karling, 1954; Schäfer, 1973). Soil samples are placed in Petri dishes and stirred with double-distilled water. Sterilized hairs or bits of snake skin are laid upon the surface. After 3–4 weeks of incubation at room temperature, the hairs are examined microscopically. When they are covered with sporangia, they are transferred onto agar. With a thin, fine-pointed tungsten needle, slightly hooked at the tip, individual sporangia are removed and rolled in zig-zag curves over the surface of agar to remove bacteria, before transferring them to a suitable growth medium, such as 5% diluted skim milk-mineral agar containing cattle horn meal (Schäfer, 1973; Vobis, 1992) or Emerson's yeast extract-starch agar (Kane, 1966). Colonies of 1 mm in diameter can be transferred onto slants after about 3 weeks. Garrity et al. (1996) transferred the infected baits to sterile Whatman filter discs and washed them under vacuum on a mini-sieve. After a period of drying of 7–10 d, the filter discs with baits are suspended in 10 ml in a small Petri dish and incubated for 45–60 min at 22°C. The solutions are diluted (10^{-1} to 10^{-3}) and plated onto suitable or selective agar medium.

Maintenance procedures

Colonies growing on agar media must be subcultured after 4–5 weeks because autolysis of vegetative mycelium may occur after 2 weeks of incubation. For long-term preservation, *Pilimelia* strains must be lyophilized.

Procedures for testing special characters

The ability to decompose keratinic substances can be tested with hair of white mice. Sterilized hairs are incubated together with mycelium and checked microscopically after 2 weeks. Damaged hair segments are stainable with cotton blue (aniline blue) (Gams et al., 1980). Usually, the hairs are also deformed and splintered in the longitudinal axis (Figure 223G).

Differentiation of the genus *Pilimelia* from other related genera

The genus *Pilimelia* has a unique taxonomic position among the sporangiate genera belonging to the family *Micromonosporaceae*. It can be differentiated by morphological, physiological, and chemotaxonomic criteria. The genera *Dactylosporangium*, *Planosporangium*, and *Virgisporangium* can be separated from *Pilimelia* because they have oligospore sporangia with 2–6 or more spores per sporangium, organized in a single row. Among the polysporous sporangia producing genera of *Micromonosporaceae*, *Luedemanella* can be distinguished by the formation of nonmotile sporangiophores. *Actinoplanes*, which also forms polysporous sporangia with motile sporangiophores, produces globose or rod-like spores; *Pilimelia* spores are exclusively rod-like. The distinguishing properties are the size of the spores and the type of flagellation: the spores of *Pilimelia* are 0.3–0.7 × 0.7–1.5 µm with a laterally tuft of flagella, whereas the rod-like spores of *Actinoplanes*, characterizing the formerly "*Ampullariella*" species, are 0.5–1.0 × 2.0–4.0 µm and equipped with a polarly inserted tuft of flagella (Vobis, 1989b). In comparison to other members of *Micromonosporaceae*, the growth of *Pilimelia* strains is very slow; they need natural keratinic substances to produce well developed colonies (Vobis, 1989a, 1992). The menaquinone composition of MK-9(H_2) and MK-9(H_4), characteristic of type 4a of Kroppenstedt (1985), differentiates *Pilimelia* from other genera of the *Micromonosporaceae*, including *Micromonospora*, *Actinoplanes*, *Catellatospora*, *Catenuloplanes*, *Couchioplanes*, *Dactyloporangium*, *Spirilliplanes*, and *Verrucosispora* (Kudo, 2001). The pattern of fatty acids is also significantly different from those of other genera with high amounts of C15 and C17, and a lack of C18 fatty acids, corresponding to type 2b of Kroppenstedt (1985).

Taxonomic comments

Members of the genus *Pilimelia* were discovered by Karling (1954), Gaertner (1955), and Rothwell (1957), who were studying hair of mammals attacked by unusual, keratinophilic micro-organisms. Only preliminary diagnoses could be made, since pure cultures were not obtainable at this time. After successful culturing of single strains, Kane (1966) described the genus *Pilimelia* based on two species, *Pilimelia terevasa* and *Pilimelia anulata*. According to the original descriptions, the type strains appeared to be keratinophilic members of the genus *Ampullariella* (Cross and Goodfellow, 1973). This questionable taxonomic position could be clarified by re-examination of the type strains in connection with the description of a third species, *Pilimelia columellifera* (Schäfer, 1973; Vobis et al., 1986b). Finally, the recognition of the genus *Pilimelia* was supported by chemotaxonomic and phylogenetic investigations (Koch et al., 1996a; Kroppenstedt, 1985).

The proposals to transfer *Pilimelia terevasa* and *Pilimelia anulata* to "*Ampullariella*" (Juan and Zhang, 1974), and *Pilimelia columellifera* (Schäfer, 1973) to *Spirillospora* (Tribe and Abu El-Souod, 1979) were not considered in the Approved Lists of Bacterial Names (Skerman et al., 1980).

Differentiation of species of the genus *Pilimelia*

The species of *Pilimelia* are distinguishable by morphological and colonial criteria. Differential characteristics are listed in Table 200. Other physiological characters of the species and subspecies are indicated in Table 201.

List of species of the genus *Pilimelia*

1. **Pilimelia terevasa** Kane 1966, 225[AL]

ter.e.vas′a. L. adj. *teres* rounded (i.e. circular in transverse sections, tapering or narrow cylindric); L. pl. n. *vasa* vessels; N.L. n. *terevasa* rounded vessels, indicating "rounded", spherical sporangia.

Sporangia develop on hair of mammals floating on soil–water and on artificial soil extract agar. The shape of sporangia is spherical (type strain) or campanulate (Figure 223). The sporangia can reach diameters of up to 24 µm. The rod-shaped spores (0.3–0.6 × 0.7–1.5 µm) are motile by means of a tuft of laterally inserted flagella. Spores are released after 15–20 min from sporangia when flooded with water. Sporangiophores are septate, approximately 1 µm in diameter.

Colonies on agar media are bright lemon-yellow with rough lobed borders. The surface is tuberculate and warty with curled protrusions. The consistency is soft and pasty.

Source: the type strain was isolated from a soil sample collected in the area of St. Joseph Co., Indiana (USA).

DNA G+C content (mol%): unknown.

Type strain: ATCC 25603, CBS 570.75, DSM 43040, NBRC 15964, JCM 3091, KCC A-0091.

Sequence accession no. (16S rRNA gene): X93190.

2. **Pilimelia anulata** Kane 1966, 225[AL]

an.u.la′ta. L. fem adj. *anulata* having a ring.

Sporangia develop on mammalian hair and on agar media, supported by septate sporangiophores, where the uppermost fragment is swollen to a ring-like structure (Figure 223A, C). The sporangia are cylindrical, 2.8–11.2 µm wide and up to 35 µm long. Inside the sporangium, the spores are arranged in parallel chains. The spores are rod-shaped (0.3–0.7 × 0.8–1.3 µm) and equipped with a laterally inserted tuft of flagella. Conidiophores with conidia in chains (Figure 223D) are occasionally produced.

Colonies on agar media are bright lemon-yellow to yellow-gray and with lobed margins. The surface of the colonies is tuberculate with narrow and often branched, curled protrusions. The consistency is soft and pasty.

Source: the type strain was isolated from a soil sample collected in the area of St. Joseph Co., Indiana (USA).

DNA G+C content (mol%): unknown.

Type strain: ATCC 25604, DSM 43039, NBRC 16051, NBRC 15533, JCM 3090, KCC A-0090, NCIMB 12892.

Sequence accession no. (16S rRNA gene): X93189.

3. **Pilimelia columellifera** (*ex* Schäfer 1973) Vobis, Schäfer, Kothe and Renner 1986a, 573[VP] (Effective publication: Vobis, Schäfer, Kothe and Renner 1986b, 72.) (Schäfer 1973, 190.)

co.lu.mel.li′fe.ra. L. n. *columella* small column; L. suff. *-fer -fera -ferum* carrying; N.L. fem. adj. *columellifera* bearing a small column.

Sporangia are produced on the surface of hair and on agar media (Figure 223F). The shape of sporangia is spherical, ovoid, or pyriform and 7–16 µm in diameter. Sporangiophores develop in chains that are arranged like swirls. The nonseptate sporangiophore is extended into the lumen of the sporangium, thus forming a columella (Figure 223A). If sporangia are dipped into the water, spores start to swarm after 45 min. Occasionally, swarming occurs inside the sporangia until finally the envelope tears and the spores escape. The rod-shaped zoospores (0.35–0.45 µm wide and 0.8–1.5 µm long) are motile by means of two to four laterally inserted flagella.

Colonies on agar media are small, about 5 mm in diameter after 4 weeks of incubation. They are compact, irregular, and pulvinate. The surface is warty and squamous, and the consistency is solid. The color of mycelium is golden yellow to orange or colorless to pale brownish. The type strain shows the highest sequence similarity to *Micromonospora pattaloongensis* TJ2-2^{T} (97.3%), *Micromonospora auratinigra* TT1-11^{T} (97.2%), and *Polymorphospora rubra* (97%).

Source: Pilimelia columellifera was preliminarily described as "organism I" by Gaertner (1955), and could be registered by enrichment culture in 45 soil samples collected in Africa and in one sample from Germany. Tribe and Abu El-Souod (1979) reported the frequent presence of the species in soil samples collected in the Cambridge region (England).

DNA G+C content (mol%): unknown.

Type strain: ATCC 43728, CBS 569.75, DSM 43797, NBRC 16052, JCM 3367, MB-SK6.

Sequence accession no. (16S rRNA gene): AB548688.

3a. **Pilimelia columellifera subsp. columellifera** (*ex* Schäfer 1973) Vobis, Schäfer, Kothe and Renner 1986a, 573[VP] (Effective publication: Vobis, Schäfer, Kothe and Renner 1986b, 72) (Schäfer 1973, 190.)

The description is as for the species. It differs from the subspecies *Pilimelia columellifera* subsp. *pallida* by its golden yellow to orange substrate mycelium and by its ability to reduce nitrate.

Source: the type strain originated from a soil sample from Peru; a further 19 strains were isolated from soil samples collected in Germany, British Isles, Ceylon, Spain, Greece, Yugoslavia, Israel, Persia, and Austria (Schäfer, 1973).

DNA G+C content (mol%): unknown.

Type strain: ATCC 43728, CBS 569.75, DSM 43797, NBRC 16052, JCM 3367, MB-SK6.

Sequence accession no. (16S rRNA gene): AB548688.

3b. **Pilimelia columellifera subsp. pallida** (*ex* Schäfer 1973) Vobis, Schäfer, Kothe and Renner 1986a, 573[VP] (Effective publication: Vobis, Schäfer, Kothe and Renner 1986b, 72.) (Schäfer 1973, 192.)

pal′li.da. L. fem. adj. *pallida* pale.

The subspecies *pallida* is distinguishable from *Pilimelia columellifera* subsp. *columellifera* by a colorless to pale brownish substrate mycelium. The center of the colonies occasionally becomes blackish with increasing age. Colonies are flat or convex to slightly raised and umbonate. Sporangial development occurs occasionally on oatmeal-yeast extract agar or on artificial soil extract agar. Melanoid pigments are produced on peptone-yeast extract-iron agar and on tyrosine agar. Nitrate is not reduced to nitrite.

Source: the type strain was isolated from a soil sample collected in Germany; in addition, three further strains were isolated from soil in Germany and Portugal (Schäfer, 1973).

DNA G+C content (mol%): unknown.

Type strain: DSM 43799, MB-SK8.

Sequence accession no. (16S rRNA gene): not available.

Genus XIII. **Polymorphospora** Tamura, Hatano and Suzuki 2006, 1961[VP]

Tomohiko Tamura

Po.ly.mor.pho.spo′ra. Gr. adj. *polumorphos* multiform; Gr. fem. n. *spora* seed, and in biology, a spore; N.L. fem. n. *Polymorphospora* polymorphic spore.

Gram-stain-positive, not acid-fast, producing a fine, nonfragmenting, branching mycelium. Strictly aerobic. **Short spore chains** develop on short sporophores on the substrate mycelium. Immature spores are **oval or of various shapes**, and **short rods** are formed (0.6–0.9 × 0.8–1.5 µm wide) on maturation. Spores are **nonmotile**. Optimum temperature for growth generally ranges between 20 and 30°C. Cell wall contains D-glutamate, glycine, D-alanine, and *meso*-diaminopimelate. Mannose, 3-*O*-methylmannose, glucose, and galactose are detected as whole-cell sugars. The predominant cellular fatty acid is $C_{16:0}$ iso, followed by $C_{17:1}$ and $C_{17:0}$ anteiso. The major menaquinones are MK-10(H_6), MK-10(H_4), MK-9(H_6), and MK-9(H_4). Phosphatidylethanolamine is present as the diagnostic phospholipid, whereas phosphatidylcholine is absent (phospholipid pattern type PII). The acyl type of the cell wall is glycolyl. Mycolic acid is absent.

DNA G+C content (mol%): 70–71 (HPLC).

Type species: **Polymorphospora rubra** Tamura, Hatano and Suzuki 2006, 1963[VP].

Further descriptive information

The organism shows good growth on oatmeal agar, inorganic salts-starch agar, and peptone-yeast extract-iron agar. Cultures also grow well in yeast extract-glucose broth consisting of yeast

extract (1%) and D-glucose (1%), pH adjusted to 7.0, upon incubation at 28°C on a rotary shaker for 4 d. The chemotaxonomy of the genus *Polymorphospora* is chemotype II according to Lechevalier and Lechevalier (1970a), and the peptidoglycan type is presumed to be A1γ according to Schleifer and Kandler (1972). A unique nucleotide signature includes a U at position 1244 of the 16S rRNA gene.

Enrichment and isolation procedures

Samples are inoculated on humic acid-vitamin (HV) agar (Hayakawa and Nonomura, 1987a) using the yeast extract–SDS method (Hayakawa and Nonomura, 1989). Incubation is at 28°C for 2 weeks. The described strains were isolated from soil samples collected near the roots of *Bruguiera gymnorrhiza* and *Sonneratia alba* at the mouth of the River Shiira on Iriomote Island, Okinawa, Japan (Tamura et al., 2006).

Maintenance procedures

Strains of the genus *Polymorphospora* are maintained by freezing in water containing 10–30% glycerol at −70°C. Lyophilization of suspensions in 10% skim milk +1% monosodium glutamate and liquid-drying (Sakane and Kuroshima, 1997) in 0.01 M potassium phosphate buffer (pH 7.0) containing 3% monosodium glutamate are also recommended for long-term preservation.

Differentiation of the genus *Polymorphospora* from other genera

The genus *Polymorphospora* contains *meso*-diaminopimelic acid and glycine in its peptidoglycan. Unlike members of the genera *Catenuloplanes* and *Spirilliplanes*, arabinose is not detected in whole cells (Tamura et al., 1997; Yokota et al., 1993). 3-*O*-Methylmannose is contained as a whole-cell sugar, as in the genera *Spirilliplanes* and *Virgisporangium* (Tamura et al., 2001). The genus *Polymorphospora* forms spore chains and differs in this respect from the genera *Dactylosporangium* and *Micromonospora*, which are the closest phylogenetic neighbors.

Taxonomic comments

Based on 16S rRNA gene sequence analysis, the genus *Polymorphospora* forms an independent monophyletic clade within the family *Micromonosporaceae* of the order *Micromonosporales*. In addition, the two strains isolated in the original study showed DNA relatedness higher than 70% and are accommodated in the same species (Tamura et al., 2006).

List of species of the genus *Polymorphospora*

1. **Polymorphospora rubra** Tamura, Hatano and Suzuki 2006, 1963[VP]

   ru′bra. L. fem. adj. *rubra* red.

   Colonies that develop on ISP media 2, 3, and 4 are red to reddish-orange in color. Utilizes D-mannitol, melibiose, maltose, L-rhamnose, methyl α-D-glucoside, D-galactose, D-mannose, and D-glucose. Positive in tests for starch hydrolysis and urea decomposition. No growth in the presence of 4% NaCl. Esculin is not hydrolyzed. The major cellular fatty acids are $C_{16:0}$ iso and $C_{16:1}$.

   Source: the type strain was isolated from rhizosphere soil of mangrove.

   DNA G+C content (mol%): 70–71 (HPLC).

   Type strain: TT 97-42, DSM 44947, NBRC 101157.

   Sequence accession no. (16S rRNA gene): AB223089.

Genus XIV. **Salinispora** Maldonado, Fenical, Jensen, Kauffman, Mincer, Ward, Bull and Goodfellow 2005, 1763[VP]

Paul R. Jensen, Luis A. Maldonado and Michael Goodfellow

Sa.li.ni.spo′ra. L. adj. *salinus* saline; Gr. fem. n. *spora* a seed and, in bacteriology, a spore; N.L. fem. n. *Salinispora* a spore-forming bacterium originating from a saline habitat, indicating the marine habitat of the organism.

Obligately aerobic, Gram-stain-positive, non-acid-fast, nonmotile actinomycetes that form extensively branched substrate hyphae carrying single or clusters of smooth-surfaced spores, which may be sessile or borne on short sporophores. Vegetative hyphae are finely branched but do not show any fragmentation. Strains grow well at 10–30°C and pH 7–12. Colonies range from bright to pale orange and dark brown changing to black as they sporulate with no aerial mycelia observed. Brown diffusible pigments that darken agar media are normally produced. **Whole-organism hydrolysates are rich in *meso*-diaminopimelic acid and contain major amounts of arabinose, galactose, and xylose**. **The muramic acid moiety of the peptidoglycan is glycolated**. **Cells contain: diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol as major polar lipids; tetrahydrogenated menaquinones with nine isoprene units as the predominant isoprenologue; and complex mixtures of saturated iso- and anteiso-fatty acids but lack mycolic acids. Do not grow when seawater is replaced with deionized water in standard complex growth media**. The phylogenetic position of *Salinispora*, as determined by 16S rRNA gene sequence analysis, is in the family *Micromonosporaceae*.

Source: isolated from marine sediments and benthic organisms.

DNA G+C content (mol%): 69.4–69.5 (from genome sequences).

Type species: **Salinispora arenicola** Maldonado, Fenical, Jensen, Kaufman, Mincer, Ward, Bull and Goodfellow 2005, 1764[VP].

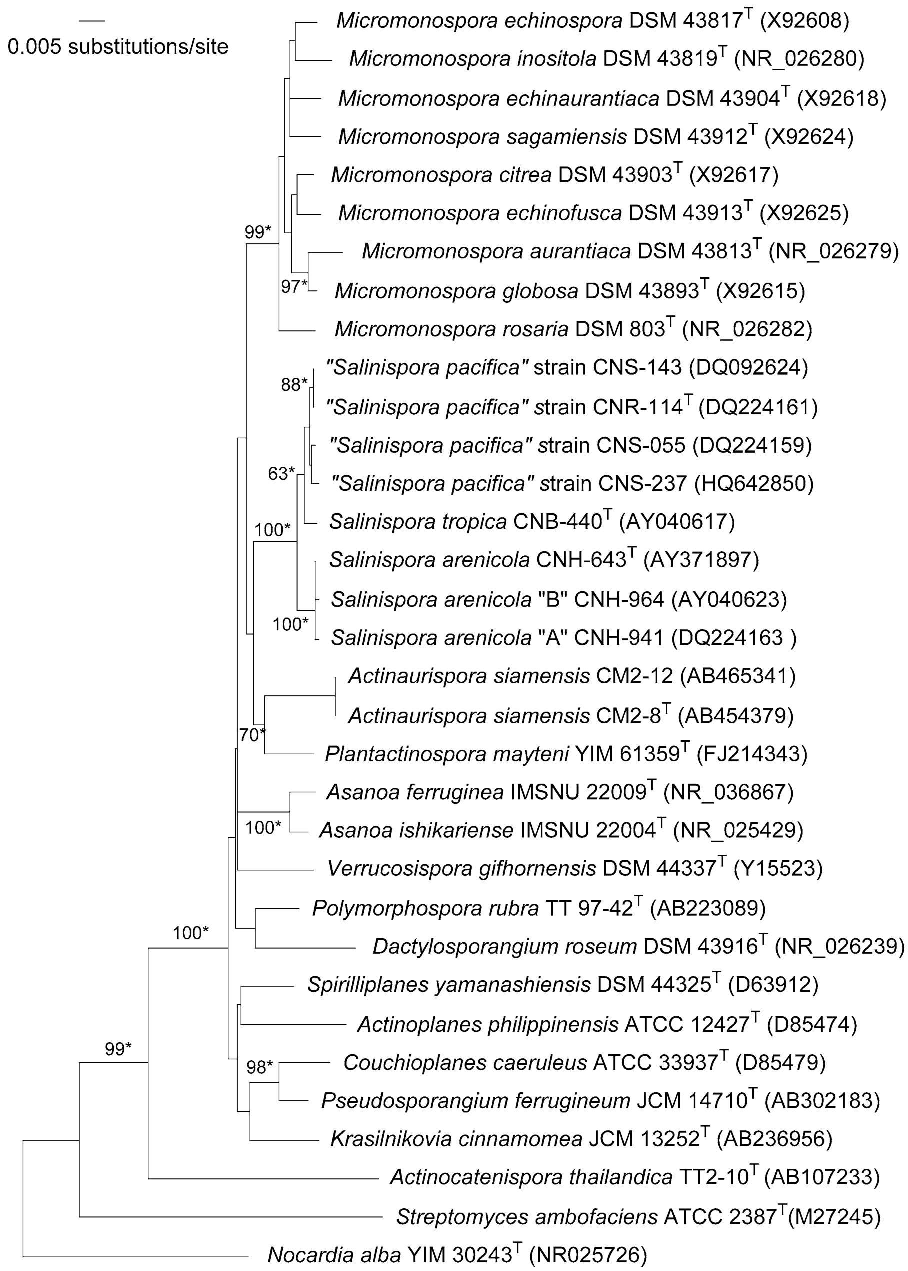

FIGURE 224. Neighbor-joining tree based on nearly complete 16S rRNA gene sequences showing relationships between *Salinispora* species and representatives of other genera classified in the family *Micromonosporaceae*. The numbers at the nodes indicate levels of bootstrap support based on an analysis of 1000 re-sampled datasets, only values above 60% are given. Asterisks indicate nodes that are also supported using the maximum-likelihood and maximum-parsimony methods. Bar = 0.005 substitutions per nucleotide position.

Further descriptive information

Phylogeny. The genus *Salinispora* forms a tight subclade in the 16S rRNA *Micromonosporaceae* gene tree (Figure 224). It encompasses two species with validly published names, *Salinispora arenicola* and *Salinispora tropica*, and a putative third species, "*Salinispora pacifica*" (Jensen and Mafnas, 2006). All *Salinispora* strains examined to date share 16S rRNA gene sequence identities greater than or equal to 99% and thereby constitute what has been described as a multidiverse ribotype cluster (Acinas et al., 2004). Initially, the genus was considered to be most closely related to the genus *Micromonospora* (Maldonado et al., 2005) but it is now known that its nearest phylogenetic neighbors are the genera *Actinaurispora* (Thawai et al., 2010) and *Plantactinospora* (Qin et al., 2009). Micromonosporae and salinisporae can also be distinguished by analysis of 16S–23S intergenic spacer regions (Maldonado et al., 2005) and by *gyrB* nucleotide sequence data (Jensen and Mafnas, 2006).

Cell morphology. *Salinispora* strains present extensively branched substrate hyphae which range from 0.25 to 0.5 µm in diameter. The substrate hyphae carry single or clusters of

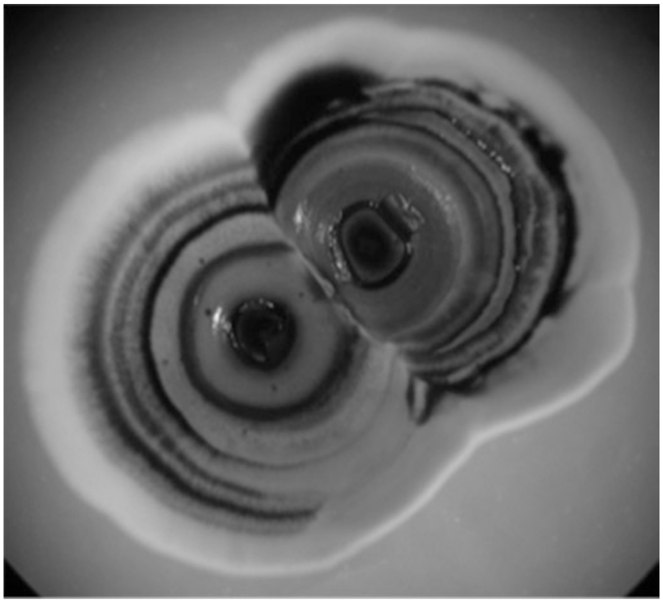

FIGURE 225. Colony of *Salinispora tropica* growing on seawater agar. Concentric rings of spores are visible on the colony surface. Photo credit: Erin Gontang.

smooth-surfaced spores. Spores range from 0.8 to 3.8 μm in diameter. Aerial hyphae have not been observed and spores may be sessile or borne on short sporophores.

Colony morphology. *Salinispora* strains grow slowly taking from 1 to 3 weeks to form small colonies on primary isolation plates (Jensen et al., 2005). Colonies are tough, leathery, and adhere to agar surfaces. On nutrient-rich media they exhibit a range of orange to brown pigments with spores blackening the colony surface (Figure 225), although on occasion poorly pigmented strains are encountered. In liquid culture, most strains are dispersed while some form dense clumps. The orange pigmentation produced in liquid culture generally fades to black over time.

Chemotaxonomy. Salinisporae contain *meso*-diaminopimelic acid as the diagnostic diamino acid of the cell-wall peptidoglycan, muramic acid residues that are *N*-glycolated, and produce whole-organism hydrolysates rich in arabinose, galactose, and xylose. They also contain diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol as diagnostic polar lipids, tetrahydrogenated menaquinones with nine isoprene units as the major isoprenologue, and complex mixtures of saturated iso- and anteiso-fatty acids, but lack mycolic acids (Maldonado et al., 2005). The predominant fatty acids (as percentages of total fatty acid content) are 13-methyltetradecanoic acid ($C_{15:0}$ iso; 3.7–13.3%), 14-methylpentadecanoic acid (C6:0; 36.4–53.5%), 16-methylheptadecanoic acid ($C_{18:0}$ iso; 3.5–10.2%), heptadecanoic acid ($C_{17:0}$; 4.1–7.8%) and 10-methyloctadecanoic acid ($C_{18:0}$ 10-methyl; 0.9–6.8%).

Nutrition and growth conditions. *Salinispora* strains were first recognized as being distinct from other actinomycetes based on their inability to grow when seawater was replaced with deionized water in the complex growth medium M4 (Jensen et al., 1991). Subsequently, it was reported that they failed to grow when sodium salts were replaced with equimolar concentrations of potassium salts suggesting a specific sodium ion requirement (Mincer et al., 2002). However, it is now clear that growth is possible at sodium concentrations as low as 5 mM (approx. 1% that found in seawater) if the medium is supplemented with sufficient concentrations of the appropriate non-sodium salts (Kim et al., 2005; Tsueng and Lam, 2008a). *Salinispora* cells are reported to lyze in the absence of a sufficiently high osmotic strength growth medium (Tsueng and Lam, 2010) and will only grow if the appropriate salts and high osmotic strength environment are provided (Tsueng and Lam, 2008b). *Salinispora* strains form well-developed colonies on media commonly employed to grow *Micromonospora* [e.g. yeast-malt extract agar (ISP medium 2); Shirling and Gottlieb, (1966)] when deionized water is replaced with seawater or an appropriate salts solution. Strains grow well on nutrient-rich agar media prepared with either natural or artificial seawater (Mincer et al., 2002).

Metabolism and metabolic pathways. *Salinispora* strains are heterotrophic and obligately aerobic. *Salinispora arenicola* and *Salinispora tropica* strains degrade arbutin, casein, elastin, gelatin, and starch, but not cellulose, chitin, tributyrin, or xylan (Maldonado et al., 2005). Similarly, cellobiose, α-lactose, melezitose, and starch are used as sole carbon sources, but not fructose, mannose, ribose, sorbose, or xylose. Salinisporae are best known metabolically for the production of secondary metabolites including the highly selective proteasome inhibitor salinosporamide A (Feling et al., 2003), which is undergoing clinical trials for the treatment of cancer (Fenical et al., 2009). Based on the analysis of two genome sequences, secondary metabolism is the major functionally annotated class of metabolic genes that differentiates the two species (Penn et al., 2009). This is supported by the observation that secondary metabolite production occurs in species-specific patterns with *Salinispora arenicola* strains producing rifamycins and staurosporines while *Salinispora tropica* strains produce salinosporamides and sporolides (Jensen et al., 2007). To date, at least 16 distinct structural types have been characterized from this genus including the cyanosporosides from "*Salinispora pacifica*" (Oh et al., 2006) and the sporolides from *Salinispora tropica* (Buchanan et al., 2005), both of which are proposed to be derived from enediyne intermediates. Other new structures from *Salinispora arenicola* include the polyketide-derived arenicolides (Williams et al., 2007) and the depsipeptide arenamides (Asolkar et al., 2009), while the antitumor antibiotic lomaivitacin (He et al., 2001) was isolated from what is now proposed to be "*Salinispora pacifica*".

Genetics. Representatives of all *Salinispora* 16S rRNA gene sequence types were originally aligned to *Escherichia coli* (accession no. J01695) and 71 type strains within the family *Micromonosporaceae*. This alignment revealed five genus-specific signature nucleotides consisting of A, C, T, T, and G (Mincer et al., 2002). This was subsequently revised to A, C, T, and G (Maldonado et al., 2005), while a new analysis including sequence data from the genera *Actinaurispora* (Thawai et al., 2010) and *Plantactinospora* (Qin et al., 2009) reveals three genus-specific nucleotides (C, T, T). Mean DNA:DNA hybridization values for *Salinispora tropica* CNB-440^T and *Salinispora arenicola* CNH-643^T are 68%. A PCR-targeted mutagenesis protocol has been developed to generate gene knock-outs in *Salinispora* species (Eustáquio et al., 2008) and used to characterize the function of enzymes involved in secondary metabolite biosynthesis in this taxon (Eustáquio et al., 2009).

Genomics. The complete genome sequences of *Salinispora tropica* strain CNB-440^T (accession no. NC_009380) and *Salinispora arenicola* strain CNS-205 (accession no. NC_009953) have been determined and analyzed (Penn et al., 2009; Udwary et al., 2007). Both chromosomes are circular with the *Salinispora arenicola* genome (5.8 Mb) being 600 kb larger in size. The *Salinispora arenicola* strain was chosen for sequencing because, unlike the type strain for this species (CNH-643^T), it produces the unusual cyclic peptide cyclomarin A (Renner et al., 1999). The two strains devote considerable proportions of their genomes (9–11%) to secondary metabolite production, which occurs in species-specific patterns (Jensen et al., 2007). Most genetic differences between the two strains are located in 21 major genomic islands, which house all of the species-specific secondary metabolic pathways. The mean nucleotide identity calculated for the two strains is 87.2%, far below the 94% value that has been suggested to delineate bacterial species (Konstantinidis and Tiedje, 2005). The genome sequences also provide evidence of marine adaptation in the form of a highly duplicated family of polymorphic membrane proteins (Penn et al., 2009). Intragenomic variability was not observed among the three copies of the 16S rRNA gene operon present in each genome.

Antibiotic sensitivity. Good growth is observed in the presence of (µg/ml) gentamicin sulfate (5 and 25), neomycin sulfate (5), streptomycin sulfate (5), novobiocin (5 and 25) penicillin G (5) and rifampin (5). *Salinispora arenicola* strains that produce compounds in the rifamycin class are also resistant to 25 µg/ml rifampin, whereas other *Salinispora* species are not.

Ecology. To date, *Salinispora* strains have only been cultured from tropical and subtropical marine environments. Most observations have been from sediments, where they have been shown to increase in abundance with depth (Jensen et al., 1991) and to occur at concentrations of $2–5 \times 10^3$ c.f.u./ml wet sediment (Mincer et al., 2005). Although the maximum depth limits are not known, strains have been successfully cultured from marine sediments collected at a depth of 1100 m (Mincer et al., 2005). Salinisporae have also been reported from a marine sponge (Kim et al., 2005) and are readily cultured from a variety of benthic marine plants and invertebrates (unpublished data, Scripps Institution of Oceanography), though there is not any evidence of specificity in these associations. The genus is broadly distributed in tropical and subtropical sediments (Jensen and Mafnas, 2006) but has yet to be cultured from more temperate environments despite culture-independent evidence that they occur in these regions (unpublished data, Scripps Institution of Oceanography). *Salinispora* species show distinct biogeographical patterns, with the only reports to date for *Salinispora tropica* coming from the Caribbean. *Salinispora arenicola* has the broadest distribution and has been recovered from all sites in which the genus has been reported, while "*Salinispora pacifica*" has an intermediate distribution, having yet to be cultured from the Caribbean (Jensen and Mafnas, 2006). Culture-independent studies have not revealed any new species-level diversity, while DNA extraction experiments have shown that most strains recovered from sediments were present as spores (Mincer et al., 2005).

Enrichment and isolation procedures

Salinispora strains are readily cultured from marine sediments using either of two approaches. The first involves drying approximately 1 g sediment at room temperature overnight in a laminar flow hood. A sterile foam plug is first stamped onto the dried sediment and then repeatedly stamped onto an appropriate agar growth medium creating a serial dilution effect. After 2–3 weeks of incubation at room temperature, *Salinispora* colonies can be seen on the agar surface. The second method involves serially diluting (1:10) 1 ml wet sediment in sterile seawater. The dilutions are then heated to 50°C for 6 min and 50 µl is spread-plated onto an appropriate growth medium using a sterile glass rod. Effective media formulations include seawater agar (1 liter natural or artificial seawater, 16 g agar) and A1 agar (10 g soluble starch, 4 g yeast extract, 2 g peptone, 16 g agar, 1 liter natural or artificial seawater). Cycloheximide (100 µg/ml final concentration) is used to supplement isolation media to reduce fungal growth, while rifampin (20 µg/ml) can be added to select for *Salinispora arenicola*, which produces related compounds in the rifamycin class and demonstrates a higher level of resistance to this antibiotic than the other taxa.

Maintenance procedures

Salinispora strains can be maintained as glycerol suspensions (20%, v/v) at −20 and −80°C for long-term preservation as suggested by Wellington and Williams (1978). The glycerol suspensions are prepared using 4–5 loopfuls of fresh biomass scraped using sterile disposable loops or sterile toothpicks from GYM or YEME agar plates that had been streaked for single colonies and incubated at 28–30°C for 10–14 d. Short-term storage can be in GYM or YEME agar slants which are inoculated from purified colonies grown at 28–30°C for 7–10 d.

Differentiation of the genus *Salinispora* from other genera

The most appropriate way of distinguishing salinisporae from other sporoactinomycetes is by PCR followed by sequencing. Suitable targets are 16S rRNA, *gyrB*, and 16S–23S rRNA intergenic spacer loci. Primers suitable for 16S rRNA gene amplification include FC27 (5′-AGAGTTTGATCCTGGCTCAG) and RC 1492 (5′-TACGGCTACCTTGTTACGACTT), as discussed by Mincer et al. (2005). *Salinispora* strains can be distinguished from well established genera classified in the family *Micromonosporaceae* using a combination of chemotaxonomic and morphological properties (see Table 190 in the treatment of the family *Micromonosporaceae*); they can also be separated from the genera *Actinaurispora* and *Plantactinospora* on this basis (Qin et al., 2009; Thawai et al., 2010). A quick and simple method is available for distinguishing between salinisporae and micromonosporae as only the latter grow on complex growth medium 4 prepared using deionized water (Jensen et al., 1991).

Taxonomic comments

The genus *Salinispora* was proposed by Maldonado et al. (2005) to accommodate representatives of large numbers of strains isolated from geographically diverse tropical and/or

subtropical locations and designated MAR1 (Mincer et al., 2002). The MAR1 strains were distinguished by morphological characteristics, 16S rRNA gene signature nucleotides, and failure to grow when seawater was replaced with deionized water in the growth medium. Comparative 16S rRNA gene sequence analysis showed that seven of the isolates formed a monophyletic clade in the family *Micromonosporaceae*, which suggested novelty at the genus level. The MAR1 isolates were provisionally assigned to a taxon that was informally designated "*Salinospora*" (Feling et al., 2003; Mincer et al., 2002).

The single most distinguishing feature of the genus is that, to date, it has only been reported from marine environments. It also appears to be unique among actinomycete genera in that strains fail to grow when seawater is replaced with deionized water in a complex growth medium or in defined media that lack specific salt combinations and a sufficiently high osmolarity (Tsueng and Lam, 2008b). Evidence that strains clading with "*Salinispora pacifica*" (M101 and SW02; Kim et al., 2005) have distinct spore arrangements relative to *Salinispora arenicola* warrants further investigation into the possibility that this is a species-defining morphological trait.

Differentiation of species of *Salinispora*

Members of the two species with validly published names can be distinguished using analysis of 16S rRNA gene sequence, DNA:DNA relatedness and phenotypic data (Maldonado et al., 2005). *Salinispora arenicola* strains, unlike those of *Salinispora tropica*, use L-proline, salicin, L-threonine, and L-tyrosine, but not galactose or inulin as sole carbon sources, and grow in the presence of 20 μg/ml rifampin. In addition, members of these taxa synthesize core-sets of secondary metabolites, *Salinispora arenicola* strains produce compounds that belong to the rifamycin and staurosporine classes whereas representatives of *Salinispora tropica* produce salinosporamides and sporalides (Jensen et al., 2007). In contrast, some "*Salinispora pacifica*" strains synthesize the structurally novel metabolites cyanosporasides A and B, salinipyrones A and B, and the polyketides pacificanones A and B (Oh et al., 2008).

List of species of the genus *Salinispora*

1. **Salinispora arenicola** Maldonado, Fenical, Jensen, Kaufman, Mincer, Ward, Bull and Goodfellow 2005, 1764[VP]

a.re.ni′co.la. L. n. *arena* sand; L. suff. -*cola* (from L. n. *incola*) inhabitant, dweller; N.L. n. *arenicola* sand-dweller, indicating isolation from marine sediments.

Aerobic, Gram-stain-positive actinomycetes, which form an extensively branched substrate mycelium that carries smooth-surfaced spores either singly or in clusters. Grows from 10–30°C; optimal growth occurs between 20 and 28°C.

Additional phenotypic properties are cited either in the genus description or in the text.

Source: isolated from coarse sand off the Bahamas.

DNA G+C content (mol%): 69.5 (from whole genome sequence).

Type strain: ATCC BAA-917, CNH-643, DSM 44817.

Sequence accession nos: AY040619 (16S rRNA gene); AY371897 (16S–23S rRNA intergenic spacer region); DQ228681 (*gyrB*); NC_009953 (genome of strain CNS-205).

2. **Salinispora tropica** Maldonado, Fenical, Jensen, Kaufman, Mincer, Ward, Bull and Goodfellow 2005, 1764[VP]

tro′pi.ca. L. fem. adj. *tropica* tropical, pertaining to the tropics, the source of the isolates.

Aerobic, Gram-stain-positive actinomycetes that form an extensively branched substrate mycelium that carries smooth-surfaced spores either singly or in clusters. Grows from 10–30°C; optimal growth occurs between 15–28°C.

Additional phenotypic properties are cited either in the genus description or in the text.

Source: isolated from sediment samples collected in the Caribbean. The type strain (CNB-440^{T}) was isolated from a sediment sample collected at a depth of 20 m off the coast of the Bahamas.

DNA G+C content (mol%): 69.4 (from whole genome sequence).

Type strain: ATCC BAA-916, CNB-440, DSM 44818.

Sequence accession nos: AY040617 (16S rRNA gene); AY371895 (16S–23S rRNA spacer region); DQ2288684 (*gyrB*); NC_009380 (whole genome of strain CNB-440^{T}).

Species *incertae sedis*

1. **"Salinispora pacifica"**

This interesting actinomycete was initially mentioned by Jensen and Mafnas (2006) but has yet to be deposited in culture collections and the name has not been validly published. Nonetheless, it provides insight into the phenotypic and phylogenetic diversity of the genus *Salinispora*. A representative of the taxon forms a distinct lineage in the 16S rRNA *Salinispora* gene tree (Figure 224) and has a range of phenotypic properties and DNA:DNA relatedness values that distinguish it from the type strains of *Salinispora arenicola* and *Salinispora tropica*. Members of this taxon have been isolated from marine sediments collected from around the islands of Guam and Palau in the Pacific Ocean (Gontang et al., 2007).

Genus XV. **Spirilliplanes** Tamura, Hayakawa and Hatano 1997, 101[VP]

Tomohiko Tamura

Spi.ril.li.plan′es. N.L. dim. neut. n. *spirillum* a small spiral; Gr. masc. n. *planes* a wanderer; N.L. fem. (*sic*) n. *Spirilliplanes* an organism with wandering cells, in spirals.

Gram-stain-positive, not acid-fast, producing a fine, nonfragmenting, branching mycelium. Strictly aerobic. The aerial hyphae **aggregate into clusters resembling coils** (Figure 226), but true sporangia are not observed; 14-d-old cultures grown on inorganic salts-starch agar have hyphae arranged in spirals of 5–10 turns with several spores per chain. Spores are ovals or short rods (0.5–0.7 × 0.7–1.0 μm) with smooth surfaces. Upon immersion in water or phosphate buffer containing soil extract, **motile spores** are released from spore chains, but in many instances motility begins over 30–60 min after spore release. **Polar flagella** are present in motile spores. In general, the vegetative mycelia are yellow to orange and aerial hyphae are white. Cell wall contains D-glutamate, glycine, D-alanine, and *meso*-diaminopimelate. Mannose, 3-*O*-methylmannose, glucose, xylose, and galactose are detected in the whole-cell sugars. $C_{17:1}$, $C_{17:0}$, $C_{15:0}$ anteiso, $C_{15:0}$ iso, and $C_{16:0}$ iso are present as major cellular fatty acids. The major menaquinone is MK-10(H_4); small amounts of MK-10(H_6) and MK-10(H_8) are also present. Phosphatidylethanolamine and phosphatidylinositol are diagnostic phospholipids (phospholipid pattern type PII). The acyl type of the cell-wall polysaccharides is glycolyl. Mycolic acid is absent.

DNA G+C content (mol%): 69 (HPLC).

Type species: **Spirilliplanes yamanashiensis** Tamura, Hayakawa and Hatano 1997, 102[VP].

Further descriptive information

The chains of very narrow and coiled sporogenous hyphae with zoospores often appear to be sporangium-like structures under a light microscope (Figure 227). Under a scanning electron microscope, however, these structures are found to be aggregated hyphae and not true sporangia (Figure 226). After incubation at 28°C for 1 h in either water or 0.01 M phosphate buffer (pH 7.0) containing 10% (v/v) soil extract, spores showed active motility.

Good growth occurs at temperatures between 25 and 30°C and on oatmeal agar, inorganic salts-starch agar, and peptone-yeast extract-iron agar.

Cultures also grow well in yeast extract-glucose broth consisting of yeast extract (1%) and D-glucose (1%), pH adjusted to 7.0, and incubated at 28°C on a rotary shaker for 4 d.

The wall chemotype is type II according to the scheme of Lechevalier and Lechevalier (1970a) and the peptidoglycan type is presumed to be type A1γ according to the classification of Schleifer and Kandler (1972).

Enrichment and isolation procedures

The type strain was isolated from a soil sample from Kofu, Yamanashi, Japan. The sample was spread on humic acid-vitamin (HV) agar (Hayakawa and Nonomura, 1987a) for isolation after dry heating (120°C, 1 h) (Nonomura and Ohara, 1969). Incubation was at 28°C for 2 weeks.

Maintenance procedures

Strains of the genus *Spirilliplanes* are maintained by freezing in water containing 10–30% glycerol at −70°C. Lyophilization of suspensions in 10% skim milk + 1% monosodium glutamate and L-drying in 0.01 M potassium phosphate buffer (pH 7.0) containing 3% monosodium glutamate (Sakane and Kuroshima, 1997) are also recommended for long-term preservation.

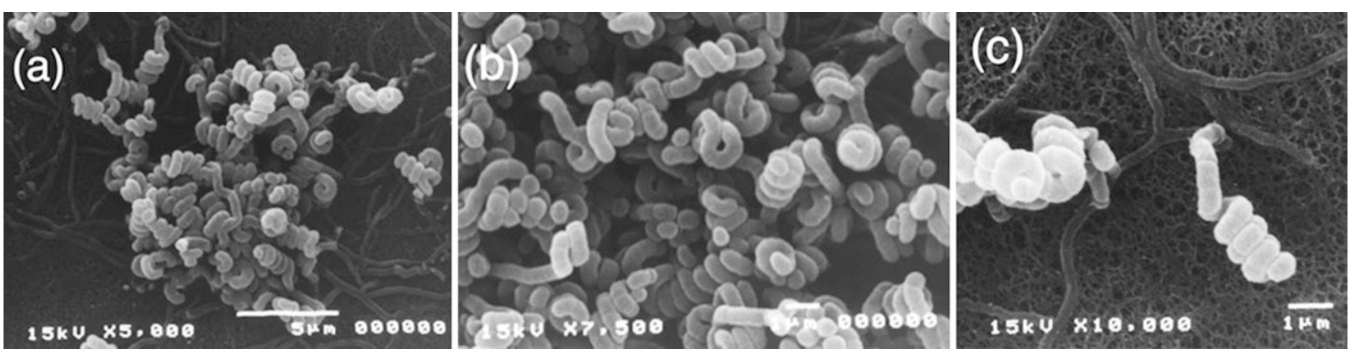

FIGURE 226. Scanning electron micrograph of a 14-d-old culture of *Spirilliplanes yamanashiensis* grown on HV agar revealed the presence of short hyphae arranged in spirals, which could arise from the substrate mycelia. The aerial mycelium at maturity formed short chains of spores (a–c), but no true sporangia were observed because the hyphae were not covered with a sheath.

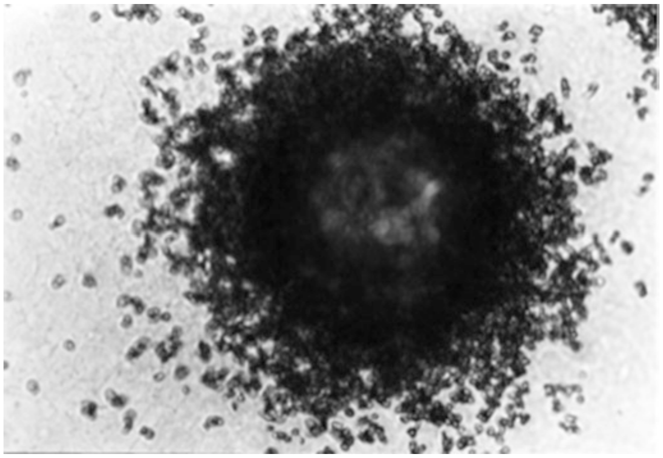

FIGURE 227. Light micrograph of a colony of a 14-d-old culture of *Spirilliplanes yamanashiensis* grown on HV agar. The sporogenous hyphae aggregate into clusters resembling sporangia under the light microscope, but are not true sporangia (see legend to Figure 226).

Differentiation of the genus from other genera

The genus *Spirilliplanes* possesses a chemotype II cell wall and chains of very narrow, coiled sporogenous hyphae with zoospores. Members of the order *Micromonosporales* with chemotype II cell walls are the genera *Actinoplanes*, *Dactylosporangium*, and *Pilimelia*, and they also have motile elements or spores. The genus *Spirilliplanes* can be distinguished from these genera because it does not form sporangia, lacks arabinose in whole cells, and possesses a different menaquinone pattern.

Taxonomic comments

Based on 16S rRNA gene sequence analysis, the genus *Spirilliplanes* clearly forms an independent lineage in the phylogenetic tree of the family *Micromonosporaceae* of the order *Micromonosporales*. The morphological and chemotaxonomic characteristics also clearly separate the genus *Spirilliplanes* from the other genera.

List of species of the genus *Spirilliplanes*

1. **Spirilliplanes yamanashiensis** Tamura, Hayakawa and Hatano 1997, 102[VP]

ya.ma.na.shi.en′sis. N.L. fem. adj. *yamanashiensis* of or pertaining to Yamanashi Prefecture, Japan, the source of soil from which the organism was isolated.

Brownish soluble pigment is produced on tyrosine agar (ISP medium 7). Liquefies gelatin. Hydrolyzes starch. Does not decompose calcium malate. Does not coagulate milk. Xylose, glucose, inositol, raffinose, rhamnose, mannitol, and sucrose are utilized, but fructose and inositol are not.

Source: soil sample from Kofu, Yamanashi, Japan.

DNA G+C content (mol%): 69 (HPLC).

Type strain: YU127-1, DSM 44325, NBRC 15828, JCM 10032, VKM Ac-1993.

Sequence accession no. (16S rRNA gene): D63912.

Genus XVI. **Verrucosispora** Rheims, Schumann, Rohde and Stackebrandt 1998, 1125[VP]

Erko Stackebrandt

Ver.ru.co.si.spo′ra. L. adj. *verrucosus -a -um* warty; Gr. fem. n. *spora* a seed and in biology a spore; N.L. fem. n. *Verrucosispora* an organism with warty spores.

Gram-stain-positive, non-acid-fast, **aerobic organism with branching hyphae**. **Well developed septate mycelium** averaging 0.4 µm in diameter. **Nonmotile spores are borne singly, sessile, or on short or long sporophores**. Warty spore surface changes to a hairy appearance with increased age. **Aerial mycelium is absent**. Strictly aerobic. Chemo-organotroph. Good growth occurs at temperatures between 30 and 40°C. The peptide side-chain of the peptidoglycan contains *meso*-diaminopimelic acid (*meso*-A_2pm), glycine, alanine, and glutamic acid. The peptide side-chains are directly cross-linked (type A1γ). The acyl type of the cell-wall polysaccharides is glycolyl. Mannose and xylose are present in whole cell hydrolysates; arabinose is absent. Characteristic phospholipids are phosphatidylethanolamine, diphosphatidylglycerol, phosphatidylinositol mannoside, and phosphatidylserine. Major menaquinone is MK-(H_4); minor amounts of MK-9(H_6), MK-10(H_4), and MK-9(H_2) are found. Major fatty acids (>15% of total) are $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso; $C_{17:0}$ iso, $C_{17:1}$ iso, and $C_{18:0}$ iso are found in minor amounts (>4% to <15%). Phylogenetically, a member of the *Micromonosporaceae*.

DNA G+C content (mol%): 70 (HPLC).

Type species: **Verrucosispora gifhornensis** Rheims, Schumann, Rohde and Stackebrandt 1998, 1126[VP].

Further descriptive information

The family *Micromonosporaceae* was phylogenetically placed in the suborder *Micromonosporineae* as one of several suborders of the order *Actinomycetales*, subclass *Actinobacteridae*, class *Actinobacteria* (Stackebrandt et al., 1997), but in the present volume the suborder has been elevated to order *Micromonosporales*, class *Actinobacteria*. The type strains of members of the most closely related genera are indicated in the phylogenetic tree

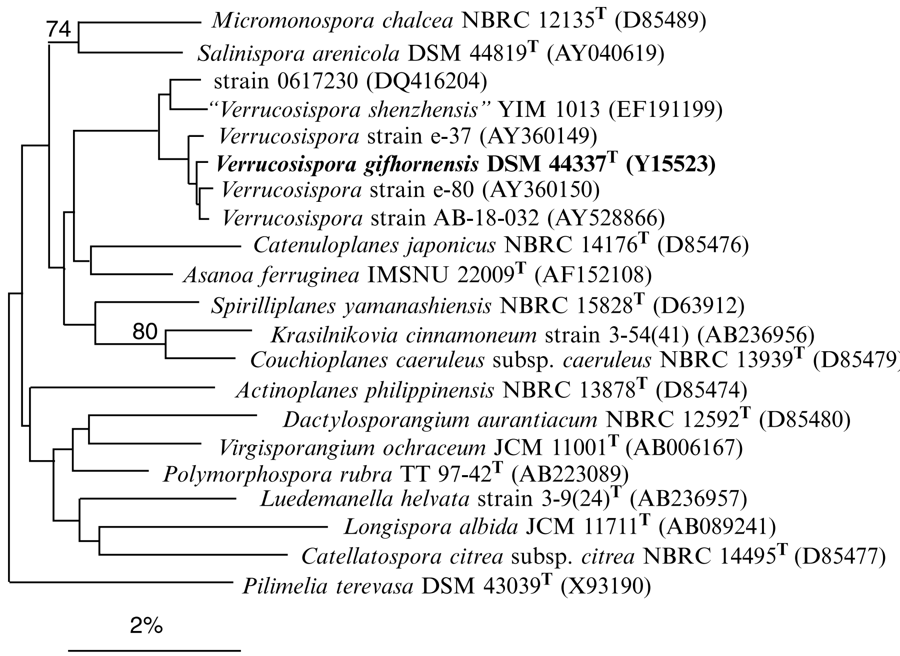

FIGURE 228. Phylogenetic tree showing the position of *Verrucosispora gifhornensis* and related strains among type strains of the family *Micromonosporaceae*, based upon 16S rRNA gene sequence analysis. The sequence of *Streptomyces ambofaciens* served as an outgroup sequence. Evolutionary distances were calculated by the method of Jukes and Cantor (1969). Phylogenetic dendrograms (DeSoete, 1983) were constructed using sequences from different sets of reference strains. Bootstrap analysis (>70% are shown) was used to evaluate the tree topology of the neighbor-joining data by performing 500 resamplings (Felsenstein, 1985). Bar = 2 nucleotide substitutions per 100 nucleotides.

based on 16S rRNA gene sequence similarities (Figure 228). All genera are closely related phylogenetically (Koch et al., 1996a; Maldonado et al., 2005; Matsumoto et al., 2003; Tamura et al., 1997, 2001, 2006; Thawai et al., 2006a), sharing >91% similarity among each other. *Verrucosispora gifhornensis* appears equally closely related (96.0–97.4%) to the majority of genera, sharing a slightly higher degree of relatedness with members of the *Catenuloplanes*, *Asanoa*, and *Spirilloplanes*. However, bootstrap values are low for most branching points indicating the low statistical significance of the branching order [see also dendrograms shown by Tamura et al. (2006) and Matsumoto et al. (2003)]. The close relatedness among type strains is also supported by DNA–DNA reassociation values. The experiments, carried between strain *Verrucosispora gifhornensis* and two close relatives, revealed 41.4% and 40.7% hybridization with the type strains of *Micromonospora olivasterospora* and *Spirilliplanes yamanashiensis*, respectively. The similarity value for the latter pair of organisms was 30.8%. A recently published 16S rRNA gene tree on the phylogenetic position of *Polymorphosporangium rubra* (Tamura et al., 2006) differs from other trees published for newly described type strains of novel genera of the *Micromonosporaceae* in that *Verrucosispora gifhornensis* represents the most deeply branching organism of the family.

Verrucosispora gifhornensis DSM 44337^T produces substrate mycelium on all media that promote growth, but does not produce aerial mycelium. The substrate mycelium is well developed. Hyphae are approximately 0.4 µm in diameter. Sporangia are not formed. On older parts, granular structures are observed on the mycelial surface. Spores are borne singly from the substrate mycelium and are 0.8 µm in diameter. The spore surface appears warty in younger states and changes to a hairy appearance with increased age (Figure 229). Spores are nonmotile.

Members of the genus are strictly aerobic. On all media tested, *Verrucosispora gifhornensis* develops orange colonies which became brownish with increased age. Best growth is observed on agar plates with Difco tryptic soy broth. Growth on the media recommended by the International *Streptomyces* Project (ISP) (Shirling and Gottlieb, 1966) is good on medium 1 (tryptone-yeast extract broth), medium 4 (inorganic salts-starch agar), and medium 5 (glycerol-asparagine agar); moderate growth is observed on medium 2 (yeast extract-malt extract agar), medium 6 (peptone-yeast extract iron agar), and medium 7 (tyrosine agar); no growth is observed on medium 3. Growth on HV-agar (Hayakawa and Nonomura, 1987a; Tamura et al., 1997) is slow. The type strain, DSM 44337^T, grows well in 0–2% NaCl, moderately in 2–4%, but fails to grow at concentrations above 4% NaCl.

No growth is observed below 20°C or above 40°C. Good growth is seen between 30 and 40°C, with optimum growth at 35°C. The pH range for growth is 6.5–8.2, with an optimum at 7.5.

Growth of *Verrucosispora gifhornensis* DSM 44337^T is inhibited by the following antibiotics. Strong inhibition (diameter of the inhibition zone: 31–50 mm): amikacin (concentration: 30 µg per disc), bacitracin (10 µg), cephalozin (30 µg), doxycycline (30 µg), gentamicin (10 µg), imipenem (10 µg), kanamycin (30 µg), neomycin (30 µg), polymyxin B (300 µg), and tetracycline

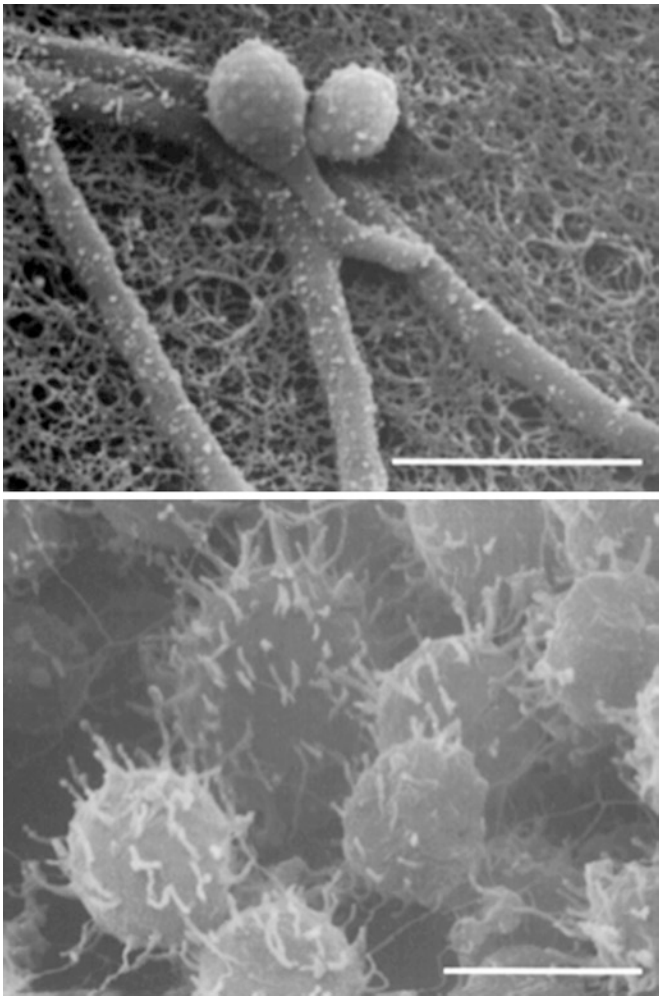

FIGURE 229. Scanning electron microscopic images of *Verrucosispora gifhornensis* DSM 44337^T. (Top) Young spores in detail; bar = 2 µm. (Bottom) Old spores in detail; the spore surface has become hairy; bar = 1 µm. (Reproduced with permission from Rheims et al., 1998. Int. J. Syst. Bacteriol. *48*: 1119–1127.)

(30 µg). Good inhibition (21–30 mm): aztreonam (30 µg), cefotaxime (30 µg), cephalothin (30 µg), norfloxacin (10 µg), penicillin G (6 µg), and ticarcillin (75 µg). Poor inhibition (10–20 mm): ampicillin (10 µg), azlocillin (30 µg), chloramphenicol (30 µg), colistin sulfate (10 µg), erythromycin (15 µg), mezlocillin (30 µg), and oflaxacin (5 µg). No inhibition is observed with lincomycin (15 µg), nitrofurantoin (100 µg), oxacillin (5 µg), or pipemidic acid (20 µg).

Strain AB-18-032, which is affiliated to the genus *Verrucosispora*, is the producer of the polycyclic polyketide Abyssomicin C. This antibiotic is an inhibitor of *para*-iminobenzoic acid biosynthesis and therefore inhibits folic acid biosynthesis at an early stage (Bister et al., 2004). Gram-stain-positive bacteria, including multiresistant and vancomycin-resistant *Staphylococcus aureus* strains, are strongly inhibited.

Enrichment and isolation procedures

Verrucosispora gifhornensis was isolated from a sample taken from a peat bog near Gifhorn, Lower Saxony, Germany (10°33′E, 52°30′N). Samples were taken from a depth of 20–40 cm after removal of the top peat layer. A dilution series of 10 g of an aged peat sample, stored at 4°C for 12 months, was set up in sterile tap water to a dilution of 10^{-6}. Aliquots of 100 µl were plated on Actinomycete isolation agar, pH 8.2 (Difco). After 11 d of aerobic incubation at 30°C, growth of strain DSM 44337^T was indicated by an expanding clear circular zone in the medium. After further incubation, an orange-red colony became visible which was transferred onto fresh Actinomycete isolation agar.

Several *Verrucosispora* strains have been isolated recently in studies exploring microbial diversity [Wang et al., (1999) (i.e. AF131629); Riedlinger et al., 2004; Fiedler et al., 2005; Rifaat et al., 2002; H Muramatsu and others, unpublished (i.e. AB123463)]. Several of these strains were isolated from the marine environment (L.A. Maldonado and others, unpublished, e.g. AY371894 and AY360149), mangrove (L.H. Liu and K. Hong, unpublished; DQ416204) and sponges (S. Jiang and others, unpublished, e.g. DQ994712). The name "*Verrucosispora shenzhensis*" has been proposed for one strain, the sequence of which is available under EF191199 (Z.L. Liao and others, unpublished). The phylogenetic position of a few strains, for which the almost complete 16S rRNA gene sequence has been determined, is shown in Figure 228. Their inter-strain relationship is >99.1%.

Maintenance procedures

Strains can be stored for some weeks as slants at 4°C and as 20% (w/v) glycerol suspensions at −20°C and −80°C. Long-term preservation methods include freeze-drying in skim milk and in liquid nitrogen at −196°C.

Differentiation of the genus *Verrucosispora* from other genera

Members of the genera can be distinguished mainly by their phylogenetic position, morphological features, e.g. presence or absence of sporangia, and motility of spores, and a combination of chemotaxonomic properties (see Table 191). The fatty acid profile of isolate DSM 44337^T is characterized by the predominance of $C_{15:0}$ iso, followed by $C_{16:0}$ iso and $C_{17:0}$ anteiso The predominance of $C_{15:0}$ iso and $C_{17:0}$ iso fatty acids over $C_{15:0}$ anteiso and $C_{17:0}$ anteiso fatty acids, the occurrence of significant amounts of unsaturated fatty acids, and the absence of 10-methyl- and 2-OH-fatty acids matches the diagnostic fatty acid type 2d (Kroppenstedt, 1985). This type has also been reported in members of the genera *Actinoplanes*, *Longispora*, *Virgisporangium*, *Actinocatenispora*, *Pilimelia*, and *Spirilliplanes*. The *meso*-A_2pm-containing, directly cross-linked peptidoglycan of the A1γ variation (cell-wall type II) is represented in all members of the family, except for members of the *Couchioplanes* and *Catenuloplanes* (type IV). The major isoprenoid quinone component, MK-9(H_4), is present in several members of the family, though often in combination with other menaquinones. The polar lipid pattern is PII (Lechevalier and Lechevalier, 1970a), consisting of the diagnostic phosphatidylethanolamine (phospholipid type PII), diphosphatidylglycerol, phosphatidylinositol mannoside, and phosphatidylserine. This combination is common among species of the family. *Verrucosispora gifhornensis* lacks arabinose among its whole cell sugars, a feature shared with members of the genera *Polymorphospora* (Tamura et al., 2006), *Catenuloplanes* (Yokota et al., 1993), and *Spirilliplanes* (Tamura et al., 1997).

List of species of the genus *Verrucosispora*

1. **Verrucosispora gifhornensis** Rheims, Schumann, Rohde and Stackebrandt 1998, 1126[VP]

gif.horn.en′sis. N.L. fem. n. *gifhornensis* of or belonging to the city of Gifhorn, adjacent to the peat bog from which the organism was isolated.

Morphological, chemotaxonomic, and general characteristics are as described for the genus. An orange pigment is produced on all ISP media tested. Gelatin liquefaction and peptonization of milk is positive. Hydrolyzes starch. Nitrite is not produced from nitrate. Cellulose decomposition is negative. D-Xylose, D-glucose, D-galactose, maltose, sucrose, D-arabinose, and α-trehalose are utilized; D-ribose, D-fructose, L-rhamnose, L-sorbose, lactose, α-melibiose, melezitose, raffinose, glycerol, dulcitol, *myo*-inositol, and salicin are not utilized. L-Serine, L-aspartic acid, L-glutamic acid, L-histidine, L-arginine, and L-phenylalanine are used as nitrogen source. Major fatty acids are (%) $C_{15:0}$ iso (31.1), $C_{16:0}$ iso (18.6), $C_{17:0}$ anteiso (16.0); minor components (>1.5% to <10%) are $C_{17:0}$ iso (8.3), $C_{17:1}$ iso (4.0), $C_{18:0}$ iso (4.4), $C_{15:0}$ anteiso (2.2), $C_{17:0}$ (2.9), and $C_{18:1}$ (1.8). The other chemotaxonomic markers are indicated in the genus description. Highly sensitive against a wide range of antibiotics.

Source: isolated from a peat bog near Gifhorn, Lower Saxony, Germany.

DNA G+C content (mol%): 70 (HPLC).

Type strain: HR1-2, DSM 44337.

Sequence accession no. (16S rRNA gene): Y15523.

Genus XVII. **Virgisporangium** corrig. Tamura, Hayakawa and Hatano 2001, 1814[VP]

Tomohiko Tamura

Vir.gi.spo.ran′gi.um. L. n. *virga* a slender green branch, rod; N.L. neut. n. *sporangium* (from Gr. n. *spora* a seed and, in biology, a spore; Gr. n. *angeion* vessel) sporangium (spore-containing vessel); N.L. neut. n. *Virgisporangium* an organism with rod-shaped sporangia (spore-containing vessels).

Gram-stain-positive, not acid-fast, produces a fine, nonfragmenting, branching mycelium. Strictly aerobic. **Slender sporangia** are formed on short sporangiophores on the substrate mycelium (Figure 230 and Figure 231). Each sporangium typically contains a single row of **six or more spores**. Spores are oval or short rods (0.6–0.9 × 0.8–1.5 µm) and exhibit motility. Cell wall contains D-glutamate, glycine, alanine, and 3-OH-diaminopimelate. Mannose, 3-*O*-methylmannose, rhamnose, glucose, arabinose, xylose, and galactose are present in whole-cell hydrolysates. The major cellular fatty acid is $C_{17:0}$ anteiso. The major menaquinones are MK-10(H_4) and MK-10(H_6). Phosphatidylethanolamine is present as the diagnostic phospholipid (phospholipid pattern type PII). The acyl type of the cell wall is glycolyl. Mycolic acid is not detected.

DNA G+C content (mol%): 71 (HPLC).

Type species: **Virgisporangium ochraceum** Tamura, Hayakawa and Hatano 2001, 1815[VP].

Further descriptive information

Good growth occurs between 20 and 30°C. In general, the vegetative mycelia are yellow to orange.

Cultures grow well in yeast extract-glucose broth, consisting of yeast extract (1%) and D-glucose (1%), pH adjusted to 7.0, and incubated at 28°C on a rotary shaker for 4 d.

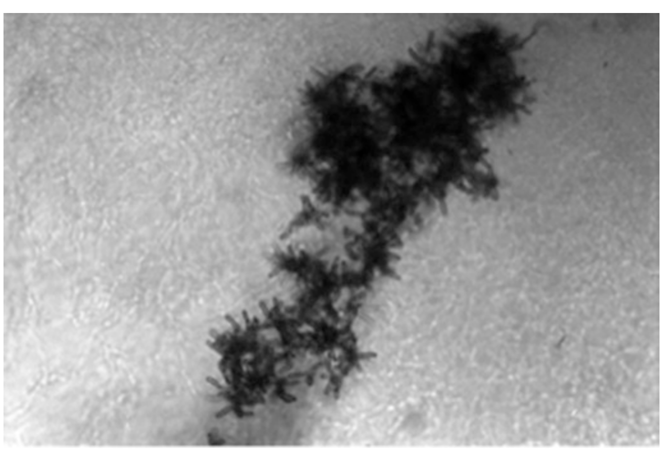

FIGURE 230. Light micrograph of 14-d-old cultures of *Virgisporangium ochraceum* isolates grown on HV agar showing rod-shaped sporangia on the substrate mycelium, which developed singly or in clusters above the surface of the substrate.

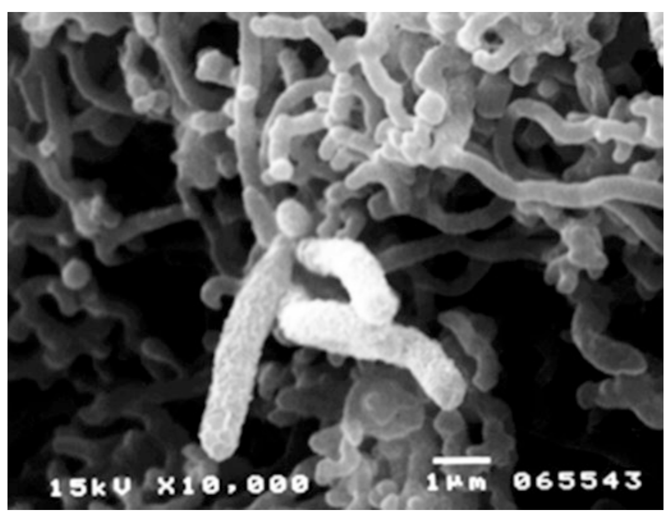

FIGURE 231. Scanning electron micrograph of 14-d-old cultures of *Virgisporangium ochraceum* isolates grown on HV agar showing that each sporangium typically contains a single row of six or more spores. Globose bodies were not observed. After incubation at 28°C for 1 h in distilled water, many spores exhibited active motility.

The cell-wall chemotype is II according to Lechevalier and Lechevalier (1970a) and the peptidoglycan type is presumed to be A1γ according to Schleifer and Kandler (1972). The cellular fatty acids are predominantly $C_{17:0}$ anteiso, with lesser amounts of $C_{18:1}$, $C_{16:0}$ iso, and $C_{15:0}$ iso, depending upon the species.

Enrichment and isolation procedures

For isolation of the strains of the genus *Virgisporangium*, samples are inoculated on humic acid-vitamin (HV) agar (Hayakawa and Nonomura, 1987a) using the capillary method (Hayakawa et al., 1991d; Palleroni, 1980) with vanillin as an attractant. Incubation is at 28°C for 2 weeks. The described species were isolated from a vegetable field soil in Yamanashi, from a mulberry field soil in Okinawa, and from a potato field soil in Okinawa, Japan (Tamura et al., 2001).

Maintenance procedures

Strains of the genus *Virgisporangium* are maintained by freezing in water containing 10–30% glycerol at −70°C. Lyophilization of suspensions in 10% skim milk + 1% monosodium glutamate and L-drying in 0.01 M potassium phosphate buffer (pH 7.0) containing 3% monosodium glutamate (Sakane and Kuroshima, 1997) are also recommended for long-term preservation.

Differentiation of the genus *Virgisporangium* from other genera

Strains of the genus *Virgisporangium* form rod-shaped sporangia on short sporangiophores, which resemble the extended sporangia of the genus *Dactylosporangium*. However, the genus *Virgisporangium* can be distinguished from the genus *Dactylosporangium* in the development of rod-shaped sporangia with six or more spores, the absence of 10-methylated fatty acids, and the presence of MK-10(H_4, H_6, H_8). Cell walls of *Virgisporangium* contain exclusively 3-OH diaminopimelic acid as the diamino acid. Some members of the genera *Micromonospora* and *Dactylosporangium* are known to have 3-OH-diaminopimelic acid as well as *meso*-diaminopimelic acid in their cell walls.

Taxonomic comments

The original spelling *Virgisporangium* (*sic*) proposed by Tamura et al. (2001), has been corrected by the List Editor, IJSEM (2001).

Based on 16S rRNA gene sequence analysis, this genus represents an independent lineage in the phylogenetic tree of the family *Micromonosporaceae* of the order *Micromonosporales*. *Virgisporangium aurantiacum* was proposed based upon a single strain. In contrast, the description of the type species *Virgisporangium ochraceum* was based upon three strains with relatively low values of DNA relatedness (40–60%), but high phenotypic and 16S rRNA gene sequence similarity (Tamura et al., 2001).

List of species of the genus *Virgisporangium*

1. **Virgisporangium ochraceum** corrig. Tamura, Hayakawa and Hatano 2001, 1815[VP]

och.ra′ce.um. L. n. *ochra* ochre, yellow ochre; N.L. neut. adj. *ochraceum* of the color of ochre, rust-colored.

Morphological, chemotaxonomic, and general characteristics are as given above for the genus. Brownish soluble pigment is produced on tyrosine agar (ISP medium 7). Gelatin liquefaction is negative. Hydrolyzes starch. Does not decompose calcium malate. Coagulation and peptonization of milk are positive. Optimum temperature for growth is 15–30°C. Grows at 37°C. Does not grow on 7% NaCl. Glucose, D-fructose, D-xylose, L-arabinose, glycerol, and mannose are utilized, but inulin is not. The major cellular fatty acids are $C_{17:0}$ anteiso, $C_{18:1}$, and $C_{15:0}$ iso, with $C_{16:0}$ iso, $C_{17:0}$, and $C_{19:0}$ in smaller amounts.

Source: soil.

DNA G+C content (mol%): 71 (HPLC).

Type strain: YU655-43, CIP 107213, NBRC 16418, JCM 11001.

Sequence accession no. (16S rRNA gene): AB006167.

2. **Virgisporangium aurantiacum** corrig. Tamura, Hayakawa and Hatano 2001, 1815[VP]

au.ran.ti.a′cum. N.L. neut. adj. *aurantiacum* orange-colored.

Morphological, chemotaxonomic, and general characteristics are as given above for the genus. Brownish soluble pigment is produced on tyrosine agar (ISP medium 7). Gelatin liquefaction is negative. Hydrolyzes starch. Does not decompose calcium malate. Coagulation and clearing of milk are positive. Optimum temperature for growth is 15–30°C. Does not grow at 37°C. Does not grow on 4% NaCl. Glucose, D-fructose, D-xylose, L-arabinose, glycerol, maltose, and mannose are utilized, but inositol, D-sorbitol, and inulin are not. The major cellular fatty acids are $C_{17:0}$ anteiso and $C_{16:0}$ iso.

Source: the type strain was isolated from soil.

DNA G+C content (mol%): 71 (HPLC).

Type strain: YU438-5, CIP 107212, NBRC 16421, JCM 11002.

Sequence accession no. (16S rRNA gene): AB006169.

Order XII. **Propionibacteriales** ord. nov.

Sheila Patrick and Andrew McDowell

Pro.pio.ni.bac.te.ri.a′les. N.L. neut. n. *Propionibacterium* type genus of the order; suff. *-ales* ending to denote an order; N.L. fem. pl. n. *Propionibacteriales* the *Propionibacterium* order.

This order is formed by elevation of the suborder *Propionibacterineae* Zhi et al. 2009. The pattern of 16S rRNA signatures defining this order consists of nucleotides at positions 127:234 (A–U), 598:640 (U–A), 657:749 (G–C), 828 (U), 829:851 (A–C), 832:854 (U–C), 833:853 (G–U), 952:1229 (C–G), and 986:1219 (U–A).

The order contains the families *Propionibacteriaceae* and *Nocardioidaceae*.

Type genus: **Propionibacterium** Orla-Jensen 1909, 337[AL] emend. Charfreitag, Collins and Stackebrandt 1988, 356.

Genus I. **Propionibacterium** Orla-Jensen 1909, 337[AL] emend. Charfreitag, Collins and Stackebrandt 1988, 356

Sheila Patrick and Andrew McDowell*

Pro.pio.ni.bac.te′ri.um. N.L. n. *acidum propionicum* propionic aid; L. neut. n. *bacterium* a small rod; N.L. neut. n. *Propionibacterium* propionic (acid) bacterium.

Pleomorphic rods, 0.2–1.5 µm ×, 1–5 µm, often diphtheroid or club-shaped with one end rounded and the other tapered or pointed; **however, cells may be coccoid, bifid, branched, or filamentous with lengths up to 20 µm**. Cells may occur singly, in pairs or short chains, in V or Y configurations, or in clumps with "Chinese character" arrangement. Swollen spherical cells resembling sphaeroplasts, up to 5–20 µm in diameter, are formed by some strains. Highly filamentous microcolonies of long, branched, septate or non-septate filaments may be formed. **Gram-stain-positive, nonmotile**, non-acid-fast, nonsporeforming. **Anaerobic-to-aerotolerant-to-microaerophilic, although some strains can grow aerobically, most grow better anaerobically**. **Chemo-organotrophic mostly with complex nutritional requirements, grow in standard complex media:** fermentation of sugars, **polyhydroxy alcohols**, or lactate produced by the fermentative activities of other bacteria (secondary fermentation) and **produce large amounts of propionic and acetic acids** which is a distinguishing feature of the genus. Lesser amounts of iso-valeric, formic, succinic, or lactic acids and carbon dioxide are also formed. **Generally catalase-positive**. **Optimum growth temperature 30–37°C**. Colonies on solid media are smooth, convex, or rough. Floccular or granular masses of variable size may be observed in liquid media. White, gray, pink, red, yellow, or orange in color. Cell-wall peptidoglycan contains either *meso-* or LL-diaminopimelic acid (DAP) as the dibasic amino acid. Tetrahydrogenated menaquinones with nine isoprene units [**MK-9(H_4)**] are the major respiratory quinones. The long-chain **cellular fatty acids are of the straight-chain saturated**, **iso- and anteiso-methyl branched types**, **principally 12- and 13-methyltetradecanoic acids ($C_{15:0}$ iso; $C_{15:0}$ anteiso);** monounsaturated acids may also be present in small amounts.

DNA G+C content (mol%): 57–70.

Type species: **Propionibacterium freudenreichii** van Niel 1928, 162[AL].

Further descriptive information

Two principal groups of organisms are traditionally described in the genus *Propionibacterium*; namely the "classical" or "dairy" (Table 202) and the "cutaneous" (Table 203) propionibacteria (Table 204). Although the phylogenetic relationship between *Propionibacterium* species based on 16S rRNA gene sequences does not mirror exactly their classification based on habitat (Figure 232), the latter is still useful for categorizing some species.

1. The "classical" or "dairy" propionibacteria: typified by strains from dairy products and used, for example, in the manufacture of hard rennet Swiss-type cheese. The genus was first described as a result of the study of propionic acid-producing bacteria isolated from cheese by a number of authors in the early 1900s (Orla-Jensen, 1909; Von Freudenreich and Orla-Jensen, 1906). They are used as starter cultures in the dairy industry and have been studied in relation to the commercial production of propionic acid. They have also been isolated from fermenting food and plant materials such as silage and fermenting olives (Cancho et al., 1980; Cancho et al., 1970; Plastourgos and Vaughn, 1957), and from soil (van Niel, 1928), including soil from rice paddy fields (Hayashi and Furusaka, 1979). Related bacteria have been found associated with nematodes in the Zebra gut (Krecek et al., 1992) and anaerobic digestors (Riedel and Britz, 1993; Sarada and Joseph, 1994). The described species *Propionibacterium microaerophilum* and *Propionibacterium cyclohexanicum*, isolated from olive mill wastewater (Koussémon et al., 2001) and spoiled off-flavor orange juice (Kusano et al., 1997) respectively, do not fit the "classical" or "dairy" propionibacteria groups based on habitat, but they are more closely related to these species based on 16S rRNA gene sequence (97.5%

*This section is an updated version of the text written by Cecil S. Cummins and John L. Johnson in the previous edition of this *Manual*, 1986.

identity between *Propionibacterium microaerophilum* and *Propionibacterium acidipropionici*; 97.1% identity between *Propionibacterium cyclohexanicum* and *Propionibacterium freudenreichii*) compared with the "cutaneous" species. Similarly, based on 16S rRNA gene sequence, *Propionibacterium australiense*, isolated from granulomatous bovine lesions (Bernard et al., 2002b) clusters with *Propionibacterium cyclohexanicum* and is more closely related to *Propionibacterium freudenreichii* than "cutaneous" species. The recently described novel species *Propionibacterium acidifaciens*, isolated from human carious dentine, clusters with *Propionibacterium australiense* on the basis of 16S rRNA gene analysis (97.7% identity; Downes and Wade, 2009).

2. The "cutaneous" propionibacteria: strains isolated from human skin, although they also colonize the mouth, genitourinary tract, and the large intestine. *Propionibacterium propionicum*, which also causes human infection, clusters with "cutaneous" species based on 16S rRNA gene sequence.

On the basis of morphology, the human "cutaneous" propionibacteria were originally assigned to the genus *Corynebacterium* (up to seventh edition of the *Manual of Determinative Bacteriology*). They were transferred from that genus to *Propionibacterium* in the eighth edition because (a) they were anaerobic, (b) propionic acid is the main metabolic product, (c) LL-DAP is present in the peptidoglycan of most species, (d) they produce C_{15} iso- and anteiso- acids as the principal fatty acids of cell lipids, and (e) they lack mycolic acids and the arabinogalactan characteristic of *Corynebacterium* sensuo stricto. Prévot (1976), however, proposed that this group of organisms, because of their pathogenic and immunomodulatory properties, should not be transferred to *Propionibacterium* but should instead be accommodated in a separate subgenus *Coryneformis* in the family *Corynebacteriaceae*. Analysis of 16S rRNA gene sequence data confirms the distinction from the *Corynebacteriaceae* and relatedness to the other propionibacteria (Charfreitag and

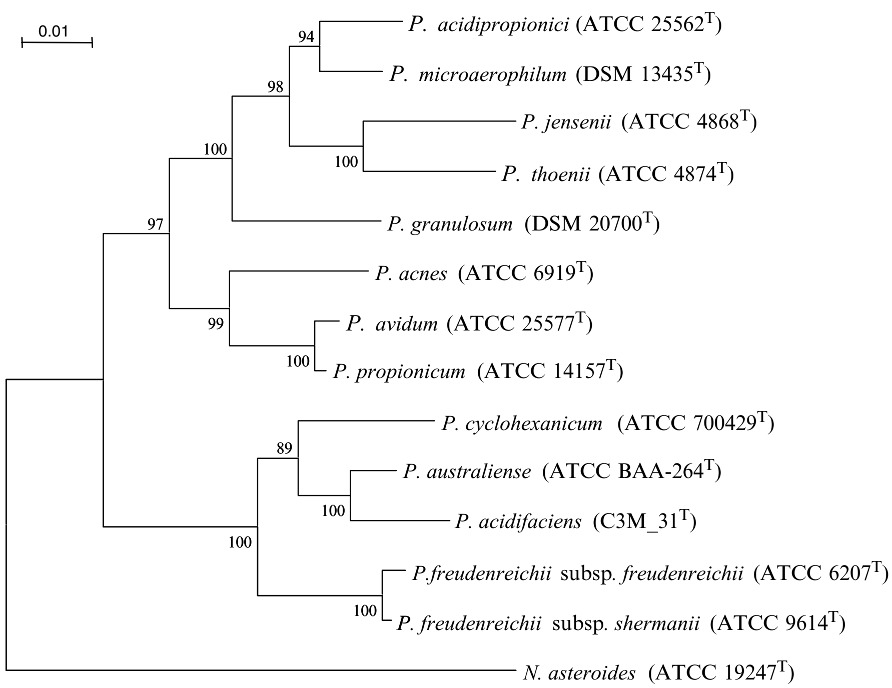

FIGURE 232. Phylogenetic tree of 16S rRNA gene sequences for the genus *Propionibacterium*. The neighbor joining tree was constructed using the Jukes–Cantor-based algorithm. The sequence input order was randomized, and bootstrapping resampling statistics were performed using 500 data sets. The 16S rRNA gene sequence from *Nocardia asteroides* was used as a distant outgroup to root the tree as it is also belongs to the class *Actinobacteria*. Bootstrap values are shown at each node of the tree. Bar = 1 substitution per 100 nucleotide positions.

Stackebrandt, 1989), and there is now general acceptance that *Propionibacterium* is a more fitting genus than *Corynebacterium* (Greenman, 1995) (see below for further discussion). This group has also been referred to as "anaerobic coryneforms", "anaerobic diphtheroids", "acnes group strains", or "cutaneous propionbacters".

In the early literature, anaerobic coryneform bacteria associated with infection were referred to as either *Corynebacterium acnes* (Douglas and Gunter, 1946) or *Corynebacterium parvum* (Cummins and Johnson, 1974). Douglas and Gunter (1946) proposed that these anaerobic coryneforms should be placed in the genus *Propionibacterium* due to the production of propionic acid, catabolic processes, and preference for anaerobic conditions, while others favored the retention of *Corynebacterium* (Puhvel, 1968). Furthermore, it is now clear that strains identified as *Corynebacterium acnes* included the two species *Propionibacterium acnes* and *Propionibacterium granulosum* (Cummins and Johnson, 1974). Cummins and Johnson (1974) also demonstrated that of 59 strains labeled *Corynebacterium parvum*, 90% were in fact *Propionibacterium acnes* by serological and physiological tests as well as DNA similarity, and almost all of the remainder were *Propionibacterium avidum*. The name *Corynebacterium parvum* has been used in immunological and oncological literature to describe the organism which has been extensively used as a reticulostimulant or immunomodulator but should be considered a synonym for *Propionibacterium acnes*. It should also be noted that the National Collection of Type Cultures (NCTC) strain 10387, still designated by the NCTC as *Corynebacterium parvum*, is identical with *Propionibacterium granulosum* ATCC 11829 (Cummins, 1980) and that NCTC 10390 (ATCC 12930), deposited as *Corynebacterium parvum*, is a strain of *Propionibacterium acnes* (phylotype II; see Table 203). We have kept much of the genus and species descriptions of Johnson and Cummins as given in the previous edition of the *Manual*, but have added to them in the light of recent molecular phylogenetic analyses. It should be noted that *Propionibacterium lymphophilum* (Torrey, 1916) has now been reclassified as *Propionimicrobium lymphophilum* (Stackebrandt et al., 2002) and *Propionibacterium innocuum* (Pitcher and Collins, 1991) as *Propioniferax innocua* (Yokota et al., 1994).

Morphologically, the "classical" propionibacteria tend to be shorter and rather thicker than the "cutaneous" species, although all strains may be very variable in morphology, especially in early exponential phase cultures. Strains of *Propionibacterium acnes* in particular give longer more slender irregular rods in young cultures, much resembling the "classical" description of *Corynebacterium diptheriae mitis*, making it easy to understand why the organism was called *Corynebacterium acnes*. In stationary phase cultures, all strains tend to be more coccal. The species *Propionibacterium propionicum* (Buchanan and Pine, 1962) and strains of *Propionibacterium acnes* phylotype III (McDowell et al., 2008) can form filaments up to at least 20 µm in length. Some strains of propionibacteria (e.g., *Propionibacterium avidum* and *Propionibacterium thoenii*) can be observed as capsulated (Skogen et al., 1974; Stackebrandt et al., 2006), and it seems that a considerable number of strains of all species may produce extracellular slime not organized in the form of clear-cut individual capsules. The extracellular material is carbohydrate in nature (Skogen et al., 1974). Purple/red polyphosphate granules may be observed by light microscopy with methylene blue stain or as electron-dense inclusions by electron microscopy with osmium staining, particularly in older cultures (Vorobjeva, 1999). Variations in the peptidoglycan composition and other sugar moieties of the cell envelopes of *Propionibacterium* species are detailed in Table 205. It has been suggested that peptidoglycan containing *meso*-DAP is related to a more coccoid morphology and LL-DAP with a coryneform morphology (Vorobjeva, 1999).

The cell lipids of both "classical" and "cutaneous" strains are characterized by the presence of large amounts of C_{15} branched-chain fatty acids (Moss et al., 1969). Mannose-containing phospholipids have been described in "*Propionibacterium shermanii*" strains (Prottey and Ballou, 1968). The mycolic acids, characteristic of the *Corynebacterium–Mycobacterium–Nocardia* group, are not found. Spermidine and spermine are the predominant compounds within the polyamine profile of the propionibacteria (Hamana, 1995).

With respect to nutritional requirements, the two groups of propionibacteria seem similar. Early studies indicated a requirement for pantothenate in all strains examined and many also require biotin, with growth generally much improved by thiamine and nicotinamide. The addition of oleate may stimulate growth and some strains require *p*-aminobenzoic acid (Delwiche, 1949; Ferguson and Cummins, 1978; Holland et al., 1979). In contrast to the auxotrophic behavior of most propionibacteria species, *Propionibacterium microaerophilum* does not require such growth factors and is, therefore, prototrophic. Amino acid requirements are complex for the "cutaneous" group (Ferguson and Cummins, 1978), but at least some of the "classical" propionibacteria can grow with ammonium sulfate as a nitrogen source (Wood et al., 1938). Most strains of propionibacteria produce vitamin B_{12}, and some, especially strains of *Propionibacterium freudenreichii*, produce large amounts (Hettinga and Reinbold, 1972; Janicka et al., 1976; Vorobjeva, 1999). Fermentation of glucose, pyruvate, dioxyacetate, and glycerol all result in propionic acid, acetic acid, and carbon dioxide production.

Bacteriophages have been reported for *Propionibacterium freundenreichii* subsp. *shermanii*; isometric and filamentous bacteriophage has been described and lysogeny demonstrated (Herve et al., 2001; Vorobjeva, 1999). Bacteriophages specific to *Propionibacterium acnes* have been used to distinguish types I and II (Webster and Cummins, 1978). The complete genome sequence of *Propionibacterium acnes* KPA171202 contains a putative pro-phage sequence (Brüggemann et al., 2004). The *Propionibacterium acnes* specific bacteriophage PA6, which has an icosahedral head and non-contractile tail characteristic of the *Siphoviridae*, has a genome sequence organization similar to the temperate mycobacteriophages, but does not appear to contain genes related to lysogeny (Farrar et al., 2007).

Isolation and maintenance procedures

Most methods for the primary isolation of propionibacteria from dairy products have relied on yeast extract-sodium lactate media (Malik et al., 1968). More complex media such as brain heart infusion broth or agar, however, have often been used for the "cutaneous" strains. Growth of all propionibacteria can be obtained in a trypticase-yeast extract-glucose medium containing 0.05% (v/v) Tween 80 (Cummins and Johnson, 1981). Defined media for the growth of propionibacteria have been devised (Ferguson and Cummins, 1978; Holland et al., 1979; Kurman, 1960; Reddy et al., 1973). A medium containing

sodium oleinate for the growth of propionibacteria and inhibition of *Actinomyces* strains from human skin swabs has been described (Kishishita et al., 1980). The addition of bromocresol purple to the medium permits identification of *Propionibacterium acnes* and other cutaneous propionibacteria which appear as yellow or slightly yellow opaque colonies with yellow zones of lysis due to the fermentation of glycerol and the production of acid. *Staphylococcus epidermidis* appears as white translucent colonies which therefore enables visual differentiation from propionibacteria. Propionibacteria can also be recovered from skin swabs using TYEG agar (2% w/v tryptone, 1% w/v yeast extract, 0.5% w/v glucose) containing furazolidone (6 μg/ml) to inhibit staphylococcal growth (Ross et al., 2003). Although some strains of propionibacteria may be aerotolerant, a culture methodology used for the primary isolation for strict anaerobes should still be adopted, such as is detailed in the Wadsworth KTL Anaerobic Bacteriology Manual (Jousimies-Somer et al., 2002). Growth media and diluents should be pre-reduced and pre-equilibrated under anaerobic conditions. The incorporation of L-cysteine hydrochloride (0.05% w/v) into liquid media and diluents provides a suitable reducing agent. An anaerobic gas atmosphere within an anaerobic jar or cabinet, from which oxygen has been scavenged by palladium catalists, should be used for incubation. A lack of adherence to strict anaerobiosis when handling and processing clinical specimens will result in reduced detection of pathogenic *Propionibacterium* species (Martin-Rabadan et al., 2008; Tunney et al., 1998). The Hungate roll tube technique (and modifications thereof), where pre-reduced anaerobically sterilized (PRAS) medium is inoculated under N_2 gas (Holdeman et al., 1977), has also been used successfully (Sarada and Joseph, 1994). The "classical" propionibacteria grow best at 30–32°C, and the "cutaneous" group strains at 36–37°C. In general, maximum growth in complex media of pure cultures is attained in 48 h; primary isolation from clinical samples may, however, require incubation for 7 d or more for the "cutaneous" group and up to 14 d for the "classical" group.

For maintenance, chopped meat medium in stoppered tubes under N_2 or another anaerobic gas atmosphere is excellent. After 48 h at the optimum temperature for growth, cultures are kept at room temperature and will maintain viability better than at +4°C (Stackebrandt et al., 2006). For maintenance it is better to omit glucose from the medium to avoid formation of excess acid. The bacterium can also be maintained successfully at −70°C on commercially available microbeads stored in a cryopreservative solution.

Differentiation of the genus *Propionibacterium* from other genera

If molecular identification methods are not used, members of the genus *Propionibacterium* may need to be distinguished from other Gram-stain-positive, nonsporeforming, nonmotile, mainly anaerobic organisms with a rather irregular morphology. Although the production of large amounts of propionic and acetic acids is generally distinctive, the following may cause confusion in some cases.

Some members of the genus *Clostridium* produce considerable amounts of propionic acid, and not all will spore freely. This refers especially to strains of *Clostridium haemolyticum*, *Clostridium novyi*, *Clostridium botulinum* types C and D, *Clostridium propionicum*, *Clostridium quericolum*, and "*Clostridium arcticum*". However, all of these, except "*Clostridium arcticum*", produce large amounts of hydrogen during growth, unlike propionibacteria which produce largely CO_2.

The other genus whose members are most likely to cause confusion is *Corynebacterium*. Here the range of G+C contents (53–67 mol%) is very similar to that in the propionibacteria, and propionic acid may be an end product of metabolism. The corynebacteria generally grow much better aerobically than anaerobically and are characterized by the presence of arabinogalactan and mycolic acids in the cell wall, neither of which is found in propionibacteria. Some corynebacteria species, however, are lacking mycolic acids; these include *Corynebacterium amycolatum* (Collins et al., 1988), *Corynebacterium atypicum* (Hall et al., 2003), *Corynebacterium caspium* (Collins et al., 2004), *Corynebacterium ciconiae* (Fernández-Garayzabal et al., 2004), and *Corynebacterium kroppenstedtii* (Collins et al., 1988). On the other hand, corynebacteria do not have the large amount of C_{15} branched-chain fatty acids in the membrane lipids which are found in propionibacteria. Three types of menaquinones have been recognized in the genus; MK-8(H_4), MK-9, and MK-9(H_4) (Yamada et al., 1976). Corynebacteria have relatively low polyamine contents, with spermidine normally the major compound (Altenburger et al., 1997).

Taxonomic comments

In relation to the "classical" propionibacteria, the species "*Propionibacterium coccoides*" shows low reassociation values in DNA–DNA hybridizations with the propionibacteria, and 16S rRNA gene sequencing indicates that it is related to *Luteococcus* (Tamura et al., 1994; Vorobjeva, 1999).

List of species of the genus *Propionibacterium*

1. **Propionibacterium freudenreichii** van Neil 1928, 162[AL] ("*Bacterium acidi propionici a*", "*Bacterium acidi propionici d*" Von Freudenreich and Orla-Jensen 1906)

freu.den.reich′i.i. N.L. gen. masc. n. *freudenreichii* of Freudenreich; named for Edouard von Freudenreich, the Swiss bacteriologist who first isolated this species.

Description based on literature descriptions including those of Sakaguchi et al. (1941), Janoschek (1944), and Werkman and Brown (1933) and on a study of two strains of *Propionibacterium freudenreichii* (Williams E1.51 and ATCC 6207) and six strains of "*Propionibacterium shermanii*" (van Niel 1.11. IAM 1714 and ATCC 8262, 9615, 9617, 13673).

Surface colonies on horse blood agar (2 d) are 0.2–0.5 μm, circular, entire, convex, semi-opaque, glistening, gray-to-white (may become cream, tan, or pink). Colonies in deep agar are lenticular-to-4 mm, white, tan, or pink. Glucose broth cultures are turbid with a smooth or granular sediment, or clear with a granular sediment, and terminal pH of 4.5–4.9. Nonhemolytic based on Vedamuthu et al., (1971).

Rarely grows on the surface of agar incubated aerobically; grows in deep broth incubated aerobically, but more slowly than anaerobically. Strongly catalase-positive.

Strains require pantothenic acid and some also require biotin and thiamine. For others, thiamine is not essential but is stimulatory, while for all strains, *p*-aminobenzoic acid is not required (Delwiche, 1949).

The major long-chain fatty acids produced in thioglycollate cultures (Moss et al., 1969) are 12-methyltetradecanoic (~43%) and a 17-carbon branched-chain acid (~12%). Will produce large amounts of free proline in peptide-containing media (Langsrud et al., 1977, 1978). Peptidoglycan contains alanine, glutamic acid, and *meso*-DAP; cell-wall sugar components are galactose and moderate amounts of mannose and rhamnose but no glucose.

Source: raw milk, Swiss cheese and other dairy products; particularly associated with the ripening, flavor and aroma of Swiss cheese.

DNA G+C content (mol%): 64–67 (T_m).

Type strain: ATCC 6207, CCUG 7433, CIP 103026, DSM 20271, HAMBI 274, LMG 16412, NBRC 12424, NCTC 10470, NRRL B-3523.

Sequence accession no. (16S rRNA gene): X53217.

Further comments: member of the "classical" or "dairy" group of propionibacteria. On the basis of 16S rRNA gene sequence analysis, *Propionibacterium freudenreichii* clusters with *Propionibacterium australiense* (isolated from bovine lesions) and *Propionibacterium cycohexanicum*, (isolated from spoiled pasteurized orange juice (Figure 232). Lipolysis generated by esterase activity ripens the cheese and the free fatty acids that are produced contribute to flavor. Carbon dioxide produced from fermentation generates the characteristic holes in, for example, Emmental cheese (Dherbecourt et al., 2008). Used commercially as a starter culture in cheese production (Benjelloun et al., 2007). Strains in this species differ broadly from the other "classical" propionibacteria in the following ways:

1. They are generally very short rods, often almost coccal in shape.
2. They are more heat resistant (Malik et al., 1968).
3. They ferment a restricted range of carbohydrates: in particular the inability to ferment sucrose and maltose seems a reliable distinction from other species.
4. Their peptidoglycan contains *meso*-DAP instead of the LL-isomer and the cell wall contains rhamnose.

1a. **Propionibacterium freudenreichii subsp. freundereichii** van Niel 1928, 162[AL] emend. Moore and Holdeman 1970

freu.den.reich′i.i. N.L. gen. masc. n. *freudenreichii* of Freudenreich; named for Edouard von Freudenreich, the Swiss bacteriologist who first isolated this species.

Description as for *Propionibacterium freudenreichii*; distinguished from subsp. *shermanii* by nitrate reduction and by a lack of lactose fermentation.

Source: raw milk, Swiss cheese and other dairy products; particularly associated with the ripening, flavor and aroma of Swiss cheese.

DNA G+C content (mol%): 64–67 (T_m).

Type strain: ATCC 6207, CCUG 7433, CIP 103026, DSM 20271, HAMBI 274, LMG 16412, NBRC 12424, NCTC 10470, NRRL B-3523.

Sequence accession no. (16S rRNA gene): X53217.

1b. **Propionibacterium freudenreichii subsp. shermanii** van Niel 1928, 162[AL] emend. Moore and Holdeman 1970 ("*Propionibacterium shermanii*" van Niel 1928, 162)

sher.man′i.i. N.L. gen. masc. n. *shermanii* of Sherman; named for James M. Sherman, an American bacteriologist.

Description as for *Propionibacterium freudenreichii*; distinguished from subsp. *freudenreichii* by lactose fermentation and a lack of nitrate reduction.

DNA G+C content (mol%): 67 (T_m).

Type strain: ATCC 9614, CCUG 36819, CIP 103027, DSM 4902, LMG 16424.

Sequence accession no. (16S rRNA gene): Y10819.

Further comments: member of the "classical" or "dairy" group of propionibacteria. Strains of *Propionibacterium freudenreichii* subsp. *freudenreichii* and *Propionibacterium freudenreichii* subsp. *shermanii* have high DNA similarity with each other (Johnson and Cummins, 1972), and there seems to be little justification for separation at the species level. Of the species described by Sakaguchi et al. (1941), it is possible that *"Propionibacterium globosum", "Propionibacterium orientum"*, and *"Propionibacterium coloratum"* were in fact other variants of *Propionibacterium freudenreichii*, but no labeled strains appear to be extant and available for testing. Complete genome sequencing of the *Propionibacterium freudenreichii* subsp. *shermanii* strain ATCC9614 (~2.6 Mb; G+C content 67%) has been undertaken (Meurice et al., 2004).

2. **Propionibacterium acidifaciens** Downes and Wade 2009, 2780[VP]

a.ci.di.fa′ci.ens. N.L. n. *acidum* an acid; L. v. *facio* to produce; N.L. part. adj. *acidifaciens* acid-producing.

Description based on three strains isolated from the human oral cavity (Downes and Wade, 2009).

Microscopically, cultures are pleomorphic rods; straight, slightly curved, or club-shaped cells are arranged singly, in pairs, or short chains with some branched diphtheroids (0.7–0.8 × 1.2–4 µm). Surface colonies are 0.7–1.1 mm in diameter, circular, entire, high-convex-to-dome-shaped, white-to-pale cream, solid, and non-translucent after 7 d growth at 37°C on fastidious anaerobe agar (LabM) supplemented with 5% (v/v) horse blood under an atmosphere of 80% N_2, 10% H_2, and 10% CO_2.

Growth is evident in peptone yeast extract broth, with moderate turbidity that is enhanced by fermentable carbohydrates (1%). In peptone-yeast extract-glucose broth, large amounts of acetic and propionic acid are produced and, in moderate amounts, succinic acid is produced.

Growth was not detectable in air enriched with 5% CO_2. Catalase-negative.

Bile tolerant, although colonies are smaller on tryptone soy agar containing 20% bile compared to tryptone soy agar only.

Source: carious lesions in the human mouth.

DNA G+C content (mol%): 70 (T_m).

Type strain: C3M_31, CCUG 57100, DSM 21887, JCM 16571.

Sequence accession no. (16S rRNA gene): AB565481, EU979537.

Further comments: based on 16S rRNA gene sequences (1442 bp), the three strains differed between one and two bases. *Propionibacterium australiense* is the most closely related species based on 16S rRNA gene sequence (97.7% identity), although the species only share 8% DNA–DNA relatedness. On the basis of RpoB amino acid sequence, *Propionibacterium acnes* is the most closely related species. The strains examined represent a homogeneous group and are representative of the dominant *Propionibacterium* taxon associated with dentinal caries (Downes and Wade, 2009). Sensitive to vancomycin and kanamycin, but resistant to colistin.

3. **Propionibacterium acidipropionici** corrig. Orla-Jensen 1909, 337[AL] ("*Bacillus acidi propionici*" von Freudenreich and Orla-Jensen 1906; "*Propionibacterium pentosaceum*" van Niel 1928; "*Propionibacterium arabinosum*" Hitchner 1932)

a.ci.di.pro.pio′ni.ci. N.L. n. *acidum propionicum* propionic acid; N.L. gen. n. *acidipropionici* of propionic acid.

Description based on the study of the type strain ATCC 25562, ATCC 4875, *Propionibacterium pentosaceum*" (van Niel 4), ATCC 4965 ("*Propionibacterium arabinosum*", Hitchner), and IAM 1725. Phenotypic characteristics of these strains are similar to original descriptions.

Surface colonies on horse blood agar after 2 d anaerobic incubation are punctiform–1 mm, circular to slightly irregular, convex, entire or slightly scalloped, gray or white, and semiopaque. Colonies in deep agar are white, becoming pink with continued incubation.

Glucose broth cultures are turbid with smooth cream-colored sediment. Terminal pH 4.1–4.9.

Usually nonhemolytic, but may show slight β-hemolysis under area of confluent growth. May grow under both aerobic and anaerobic conditions. Weak or negative for catalase (van Niel, 1957; Werkman and Brown, 1933).

Requires pantothenate and biotin for growth. Thiamine is not essential but is stimulatory (Delwiche, 1949).

The major long-chain fatty acids produced in thioglycolate cultures are 13-methyltetradecanoic acid (17–40%) and 12-methyltetradecanoic acid (12–23%) (Moss et al., 1969). Peptidoglycan contains alanine, glutamic acid, glycine, and LL-DAP as diamino acid; cell-wall sugars are glucose with galactose and/or mannose (some strain variation: see Table 5 in Johnson and Cummins, 1972).

Source: dairy products.

DNA G+C content (mol%): 66–68 (T_m).

Type strain: ATCC 25562, CIP 103025, DSM 4900, VPI 399.

Sequence accession no. (16S rRNA gene): AJ704569.

Further comments: member of the "classical" or "dairy" group of propionibacteria. On the basis of 16*S* rRNA gene sequence analysis, *Propionibacterium acidipropionici* clusters with *Propionibacterium microaerophilum* (Figure 232). The strains originally described by van Niel (1928) and Hitchner (1932) as "*Propionibacterium pentosaceum*" and "*Propionibacterium arabinosum*", respectively, show high DNA similarity with each other and are also characterized by a weak or negative catalase reaction (Cummins and Johnson, 1986). Strains of "*Propionibacterium arabinosum*" were described as being unable to ferment xylose and rhamnose, while those of "*Propionibacterium pentsaceum*" could ferment these sugars. However, as in the case of *Propionibacterium freudenreichii* and "*Propionibacterium shermanii*" with lactose fermentation, this is not considered sufficient to warrant speciation. *Propionibacterium acidipropionici* produces a high yield of propionic acid, with low acetic acid production, from glycerol fermentation and has been studied as an alternative to petrochemicals as a commercial source of propionic acid (Himmi et al., 2000).

4. **Propionibacterium acnes** (Gilchrist 1900) Douglas and Gunter 1946, 22[AL] ("*Bacillus acnes*" Gilchrist 1900; "*Corynebacterium acnes*" Eberson 1918)

ac′nes. Gr. n. *acme* a point; incorrectly transliterated as N.L. n. *acne* acne; N.L. gen. n. *acnes* of acne.

Description based on a study of several hundred strains by Holdeman et al. (1977), Cummins and Johnson (1986), including the type strain ATCC 6919, and on the results of Kishishita et al. (1979), McGinley et al. (1978), and McDowell et al. (2008, 2005).

Four distinct genetic groups have been described within *Propionibacterium acnes*. These clades, known as types IA, IB, II, and III, share over 99.9% identity based on the analysis of 16S rRNA gene sequences (1484 bp section) but can be differentiated based on polymorphisms in *recA* and a putative hemolysin/cytotoxin gene (*tly*) (McDowell et al., 2005, 2008) (Figure 233).

Colonies in deep agar appear lenticular, 4 mm or less; colonies of some strains become tan, pink or orange in 3 weeks. Surface colonies on blood (horse or rabbit) agar (2–3 d) are punctiform-to-0.5 mm, circular, entire-to-pulvinate, translucent-to-opaque, white-to-gray, and glistening. On brain heart infusion (BHI) agar, type III strains may form very small, flat, dry colonies, which are difficult to recover from the plate, in contrast to types I and II which form circular, convex, glistening, opaque colonies. Strains within the type III clade have the capacity to form long slender filaments in addition to the "classical" coryneform shape (Figure 234 and Figure 235), a characteristic not been previously described for *Propionibacterium acnes*, but known for other propionibacteria such as *Propionibacterium propionicum* (Figure 236 and Figure 237) (Pine and Georg, 1969) and *Propionibacterium australiense* (Bernard et al., 2002b). Strains of phylotype II may appear more coccoid compared to those of phylotype I and are most similar to previous descriptions of "*Clostridium parvum*" and "*Clostridium adamsoni*" which are synonyms of *Propionibacterium acnes*.

In defined medium broth culture, *Propionibacterium acnes* type IA will form a turbid suspension, while in proteose peptone yeast (PPY) or BHI broth, the organism forms a settled granular sediment (due to aggregation) with a clear solution. With increasing concentrations of glucose greater than 4%, however, aggregation is significantly reduced and the broth becomes more turbid (Patrick and Glenn unpublished). Studies with types IB and II have shown the formation of a slight fine sediment upon culture in BHI broth and a turbid solution that contains suspended cells (Cohen et al., 2005). In suitable media with good growth, the final pH is 4.5–5.0. The auto-aggregating properties of type IA strains in broth culture may reflect, in part, a hydrophobic cell surface (Cohen et al., 2005).

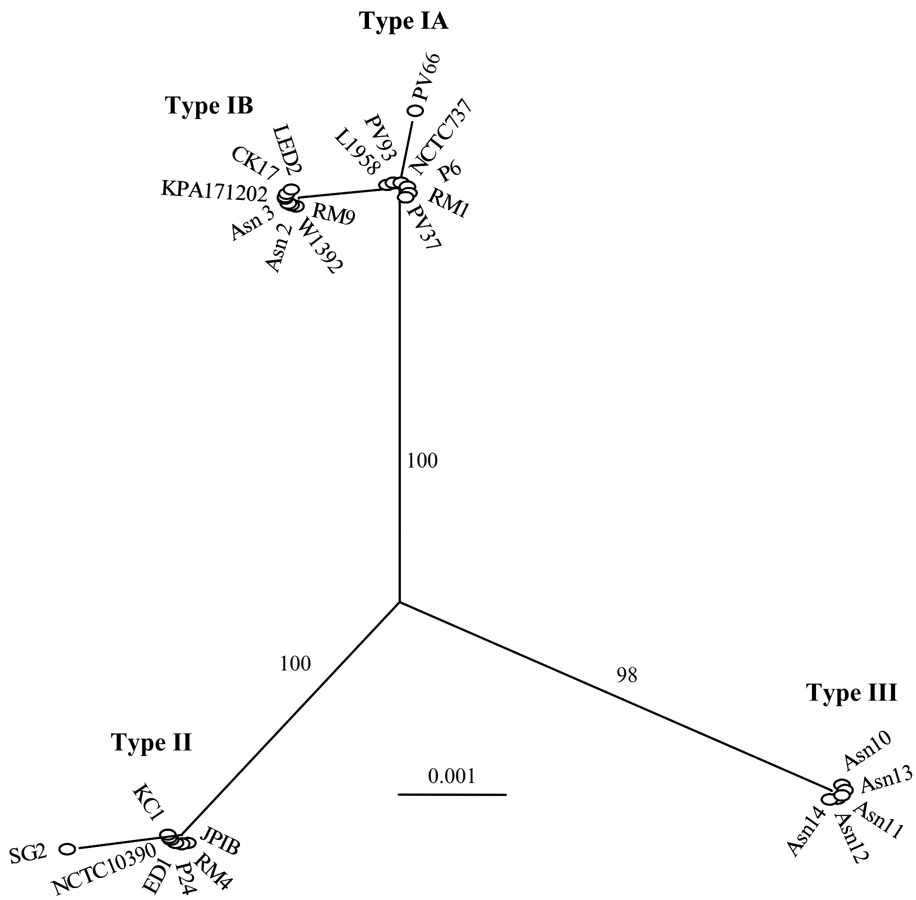

FIGURE 233. Unrooted phylogenetic tree of *Propionibacterium acnes* based on the complete *recA* gene sequence. The neighbor-joining tree was constructed using the Jukes–Cantor-based algorithm. The sequence input order was randomized, and bootstrapping resampling statistics were performed using 100 data sets. Bootstrap values are shown on the arms of the tree. The phylotype status for the different strains analyzed is shown. (Printed with permission from McDowell et al., 2008. J. Med. Microbiol. *57*: 218–224.)

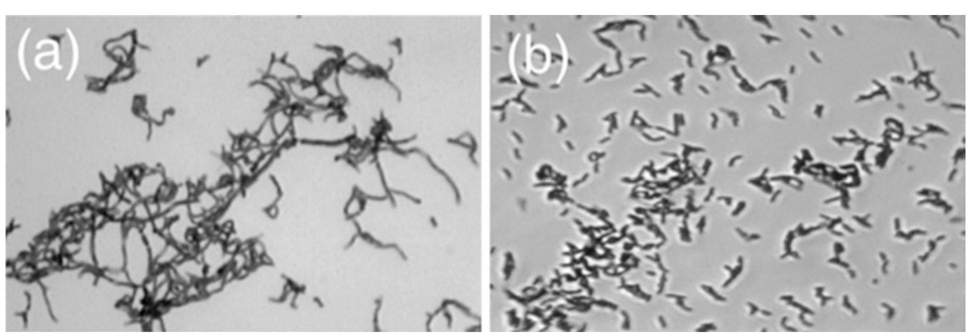

FIGURE 234. Gram stain of *Propionibacterium acnes* prepared from a mature colony (anaerobic blood agar; 7 d; 37°C); micrograph (obj. ×100). (a) Type III (Asn 10); (b) type IA (NCTC 737).

Approximately 65% of type I isolates (n=85) show β-hemolysis on horse blood, but this has not been observed with type II isolates (n=31) or any type III isolates examined to date (n=5). A gene family consisting of five homologs of the *Streptococcus agalactiae* co-hemolysin or CAMP (Christie–Atkins–Munch–Peterson)-factor has been identified within the genome of all *Propionibacterium acnes* phylotypes, and the co-hemolysin reaction similar to that originally described by Christie et al. (1944).has also been demonstrated among 50 isolates representing types IA, IB, and II (Valanne et al., 2005). Differential production of the different CAMP factor proteins has been observed among the phylotypes. In partic-

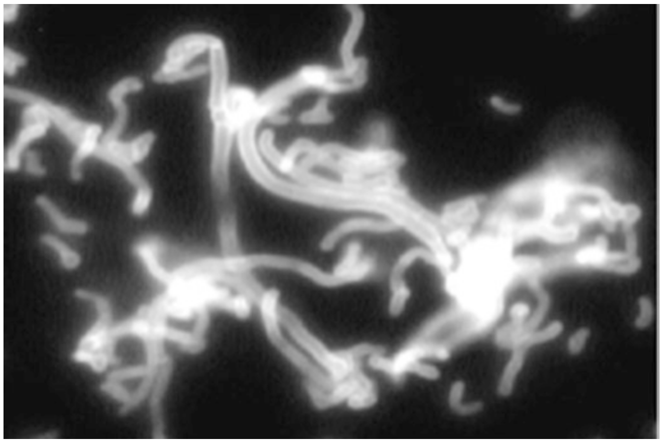

FIGURE 235. Immunolabelling of *Propionibacterium acnes* type III prepared from a mature colony (anaerobic blood agar; 7 d; 37°C); micrograph (obj × 100). Bacterium was labeled with a mouse IgG monoclonal antibody QUBPa3 (reacts with all *Propionibacterium acnes* strains) and a fluorescein isothiocyanate-conjugated goat anti-mouse IgG antibody.

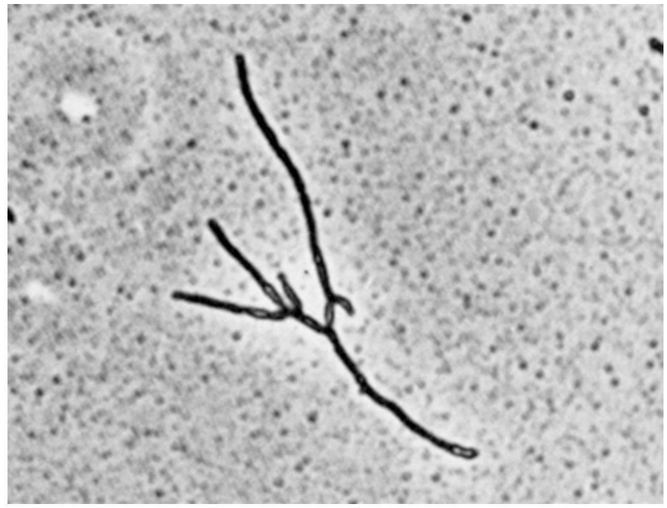

FIGURE 237. *Propionibacterium propionicum*, serovar 1. Young (20-h) microcolony on CC medium (slide culture); phase-contrast micrograph in situ (1600×).

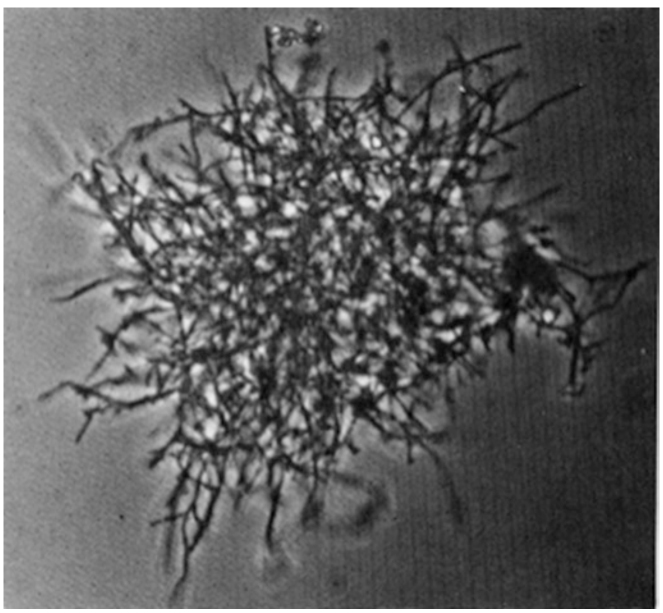

FIGURE 236. *Propionibacterium propionicum*, serovar 1. Wet mount in lactophenol cotton blue mounting fluid prepared from a 24 h culture in Tarozzi broth; phase contrast micrograph (640×).

ular, strains of type II and a commonly isolated type IB strain (ST-10 by MLST) produce large quantities of CAMP factor 1 compared to type IA organisms (Valanne et al., 2005).

The presence of oxygen is not lethal to *Propionibacterium acnes*, but anaerobiosis is usually required for isolation and growth (Cove et al., 1983). A small number of strains grow on the surface of blood agar plates incubated aerobically, while others (~30%) display variable growth on the surface of blood agar plates incubated in a candle jar for microaerophilic growth. Many strains grow in deep glucose broth without special provision for anaerobiosis. Strains are catalase-positive, although cultures need to be exposed to air for a time before testing. McGinley et al. (1978), who exposed colonies on BHI agar to air for 1 h before testing, found all 231 strains to be-positive for catalase. A study with one strain of *Propionibacterium acnes* has shown that increases in oxygen tension will alter the production of extracellular enzymes due to a decrease in growth rate (Cove et al., 1983).

The ability to ferment sorbitol is a characteristic of some type I strains, but not type II or type III strains and can, therefore, be used as a simple method of identification. On the collective basis of sorbitol, ribose, and erythritol fermentation, Kishishita et al. (1979) identified five fermentation biotypes (B1–B5) among 128 isolates of *Propionibacterium acnes* recovered from healthy facial skin. Biotypes B1-B5 were all identified among type I strains, but only B2 (ribose and erythritol fermenters) was characteristic of the type II clade. All type III strains examined to date (n=5) belong to biotype 4 (ribose fermenters) (McDowell et al., 2008).

Studies have shown that different strains produce many enzymes responsible for the degradation of host derived molecules. These include ribonuclease (Smith, 1969), neuraminidase (von Nicolai et al., 1980), hyaluronidase (Hoeffler, 1980; Ingham et al., 1980), acid phosphatase (Ingham et al., 1980) lecithinase (Werner, 1967), lipase (Ingham et al., 1981; Smith and Willett, 1968), and proteinase (Ingram et al., 1983). Analysis of the *Propionibacterium acnes* genome sequence has now identified the specific gene loci encoding these various extracellular products (Brüggemann et al., 2004). Free fatty acids released from skin lipids (e.g., sebum) by the action of lipase may (a) act as tissue irritants and (b) promote the growth of *Propionibacterium acnes* (e.g., oleate, see below). They may also assist bacterial adherence and colonization of the sebaceous follicle (Brüggemann, 2005).

Some strains also produce bacteriocin-like substances inhibitory for Gram-stain-positive and -negative anaerobes

(Fujimura and Nakamura, 1978; Ko et al., 1978; Paul and Booth, 1988).

All strains tested to date have an absolute requirement for pantothenate, while thiamine, biotin, and nicotinamide are stimulatory. Some strains of phylotype II require heme and vitamin K to grow (Ferguson and Cummins, 1978). The organic acids lactate, pyruvate, and 2-oxoglutarate also stimulate growth, as does oleate (usually used in the form of Tween 80). Amino acid requirements are complex (Ferguson and Cummins, 1978; Holland et al., 1979; Nielsen, 1983).

The major long-chain fatty acid produced in thioglycolate cultures (Moss et al., 1969) is 13-methyltetradecanoic acid (32–62%).

Peptidoglycan contains alanine, glutamic acid, glycine, LL-DAP and, in certain strains of type II, occasionally *meso*-DAP. Cell-wall sugars are glucose, mannose, and galactose. In contrast to *Propionibacterium acnes* type I, galactose is not found in the cell wall of type II strains. On the basis of differences in cell-wall composition, types I and II can be identified by serology and monoclonal antibody labeling methods (Johnson and Cummins, 1972; McDowell et al., 2005). Cell-wall sugar content of type III strains has not been determined.

Source: the bacterium primarily colonizes the sebaceous gland-rich areas of human skin, but the organism is also found in the mouth, as well as the genito-urinary tract and large intestine. In relation to infections, it has been recovered from comedones of acne vulgaris, wounds, blood, pus, soft tissue abscesses, the surface of indwelling medical devices, and eye infections. Levels of *Propionibacterium acnes* colonization on the skin vary from person-to-person and from the area of the body sampled (McLorinan et al., 2005). Levels can be as high as 10^6 organisms/cm^2, with the neck, forehead, and shoulder showing some of the highest concentrations of the bacterium compared to other sites such as the abdomen, hip, knee, and chest where levels are lower (Patel et al., 2009).

DNA G+C content (mol%): 57–60 (T_m).

Type strain: ATCC 6919, CCUG 1794, CIP 53.117, DSM 1897, JCM 6425, LMG 16711, NCTC 737, NRRL B-4224, VKM Ac-1450.

Sequence accession no. (16S rRNA gene): AB042288.

Further comments: member of the “cutaneous” group of propionibacteria. On the basis of 16S rRNA gene sequence analysis, *Propionibacterium acnes* clusters with *Propionibacterium avidum* and *Propionibacterium propionicum*. Multilocus Sequence Typing (MLST) of *Propionibacterium acnes* isolates based on the analysis of 7 core housekeeping genes (*aroE*, *atpD*, *gmk*, *guaA*, *lepA*, *recA*, and *sodA*) supports the IA, IB, II and III phylogenetic divisions (http://pubmlst.org/pacnes/; McDowell, Gao, Dowson and Patrick, unpublished). Strains of phylotypes I and II share DNA–DNA hybridization values of 88–99%. DNA–DNA hybridization values for phylotype III versus type I and II have not been determined. The *Propionibacterium acnes* genome sequence (type IB strain KPA171202; ST-10 by MLST) has revealed the presence of genes for oxidative phosphorylation, the Embden-Meyerhof and pentose phosphate pathways, and the tricarboxylic acid cycle (Brüggemann et al., 2004). Systems for anaerobic respiration, such as nitrate reductase, are also present. Reconstruction of the metabolic pathways in the bacterium demonstrates its capacity to deal with changing oxygen tensions and confirms laboratory observations (Cove et al., 1983).

Although the role of *Propionibacterium acnes* in the inflammatory condition acne has been debated, its involvement is generally accepted since acne which is refractory to antibiotic treatment is associated with strains resistant to the same antibiotic (Eady et al., 1989). Other conditions associated with *Propionibacterium acnes* include opportunistic biofilm infections of medical implants such as prosthetic joints (Tunney et al., 1998), native and prosthetic heart valves (Clayton et al., 2006), intravascular catheters (Martin-Rabadan et al., 2008), central nervous system shunts (Brook and Frazier, 1991), and also endophthalmitis post-eye surgery (Aldave et al., 1999). It has been also linked to synovitis-acne-pustulosis-hyperostosis-osteitis (SAPHO) syndrome (Kotilainen et al., 1996), sarcoidosis (Eishi et al., 2002), and chronic infection of the prostate gland, potentially leading to prostate cancer (Cohen et al., 2005). The possibility of wide variation in the potential for virulence among different *Propionibacterium acnes* isolates should not be discounted. The heterogeneity of *Propionibacterium acnes* in relation to putative virulence determinants is well documented (Lodes et al., 2006; McDowell et al., 2008; Valanne et al., 2005). Variation in expression of immune-reactive surface and secreted proteins has been described. For example, variation of proteins that bind to dermatan sulfate with carboxy-terminal repeats and the amino acid motif LPXTG, characteristic of MSCRAMMs (microbial surface components recognizing adhesive molecules), is generated by a variable number of C residues in a C_nTC_n motif upstream of the putative signal peptide for the proteins. In addition, there are variable numbers of repeats towards the mid-region and the carboxy-terminus that alter molecular mass and expression of the proteins (Lodes et al., 2006). This variation is probably generated by slipped strand mispairing during replication leading to phenotypic variation.

The strong pro-inflammatory nature of *Propionibacterium acnes* has been known for some time and homologs of GroEL, DnaK, and several other heat-shock proteins (Graham et al., 2004), which are major targets for the immune system, are present in the genome (Brüggemann et al., 2004). Three gene clusters putatively involved in extracellular polysaccharide biosynthesis have been identified in the genome sequence and may also be important in modulating immunogenicity. The production of porphyrins may lead to inflammation and generate toxic reduced oxygen species that cause cell damage. The immunostimulatory activity and adjuvant properties of isolates previously, and currently by some authors, referred to as “*Corynebacterium parvum*” are exploited in studies of the inflammatory response (Fink et al., 2008). *Propionibacterium acnes* has also been used as a non-specific immune stimulant in the equine industry (EqStim; Flaminio et al., 1998).

Propionibacterium acnes is often dismissed as a skin contaminant when present in clinical samples, especially when

present in low numbers. This has undoubtedly led to an under-reporting and, consequently, under-recognition of its association with different infections and conditions in the literature. Furthermore, many samples are not routinely cultured under anaerobic conditions. The use of protocols for anaerobic handling and isolation from clinical material increases the isolation of *Propionibacterium acnes* from clinical samples (Tunney et al., 1998). It has been demonstrated that aerobic incubation of agar plates inoculated with clinical specimens for up to 96 h prior to anaerobic reincubation will result in reduced *Propionibacterium acnes* colony numbers (Martin-Rabadan et al., 2008). This may have ramifications for the detection of *Propionibacterium acnes* associated with clinical samples that contain lower levels of the bacterium. In addition, the use of prophylactic antibiotics may also hinder growth of the organism from tissue samples. For phylotype III strains, the filamentous-like cellular morphology observed upon routine Gram-staining (Figure 234) and colony appearance (see above) may also confuse identification. When anaerobic growth from samples is performed, agar plates should be incubated long enough to observe growth (7–14 d). Infection of indwelling medical devices due to *Propionibacterium acnes* may also be under-described due to inappropriate sampling of the device and failure to detect the bacterium growing as an adherent biofilm (Tunney et al., 1998, 1999, 2007).

Analysis of isolates causing surgical, foreign body, and septicemia infections in Europe found that 3% were resistant to tetracycline, 15% to clindamycin, and 17% to erythromycin, while none were resistant to linezolid, benzylpenicillin, or vancomycin (Oprica and Nord, 2005). A study of acne patients in Europe found that the widespread use of topical formulations of erythromycin and clindamycin to treat this skin condition has resulted in a significant dissemination of cross-resistant propionibacteria strains. With the exception of Sweden and the UK, resistance rates to the orally administered tetracycline group of antibiotics are low (Ross et al., 2003). Similar results have also been described among acne patients being treated in Asia (Ishida et al., 2008; Tan et al., 2001). Resistance to erythromycin was most commonly encountered, and erythromycin-resistant strains were frequently cross-resistant to clindamycin. Among the tetracycline group of drugs, the mean MICs were higher than that for doxycycline and minocycline (Tan et al., 2001). Strains of *Propionibacterium acnes* are resistant to metronidazole (Chow et al., 1975), sulfonamides (Pochi and Strauss, 1961), and aminoglycosides (Wang et al., 1977). Studies have also shown that susceptibility of *Propionibacterium acnes* to common antimicrobials decreases as the bacterium forms a biofilm (Coenye et al., 2007; Ramage et al., 2003).

5. **Propionibacterium australiense** Bernard, Shuttleworth, Munro, Forbes-Faulkner, Pitt, Norton and Thomas 2002a, 1915[VP] (Effective publication: Bernard, Shuttleworth, Munro, Forbes-Faulkner, Pitt, Norton and Thomas 2002b, 45.)

aus.tra.li.en′se. N.L neut. adj. *australiense* of or belonging to Australia, the country where the bacterium was first isolated.

Description based on the literature description of the type strain 98A072 and the study of six strains in total (Bernard et al., 2002b; Forbes-Faulkner et al., 2000).

Microscopically, cultures are pleomorphic rods with filamentous, branching, and curved forms sometimes evident. Surface colonies grown on pre-reduced brain heart infusion agar supplemented with 5% sheep blood (BHI) under anaerobic conditions at 35°C are off-white or cream, rounded, convex, and do not adhere to the agar surface. Growth is evident in peptone-yeast broth with and without glucose. Nonhemolytic on sheep blood agar and negative for the CAMP and reverse CAMP reactions.

Growth is optimal under strict anaerobiosis and poor or non-existent in air enriched with 5% CO_2. Primary isolation from material derived from bovine granulomatous lesions required 5 d incubation on pre-reduced BHI agar. Good growth is, however, obtained within 24–48 h with repeated subculture. Catalase-negative. Peptidoglycan contains *meso*-DAP.

Source: granulomatous bovine lesions located throughout the animals (0.5–15 cm in diameter), from cattle in Queensland, Australia.

DNA G+C content (mol%): not available.

Type strain: 98A072, NML 98A072, ATCC BAA-264, CCUG 46075.

Sequence accession no. (16S rRNA gene): AF225962.

Further comments: all six strains examined had identical 16S rRNA gene sequences (>1460 bp) and cluster with *Propionibacterium acidifaciens* and *Propionibacterium cyclohexanicum* (Figure 232). These granulomatous lesions were distinguishable from those caused by *Mycobacterium bovis*, *Rhodococcus equi*, *Actinomyces bovis*, and fungi. The lesions consisted of a characteristic fibrous outer capsule surrounding thick yellow viscous pus with caseating granulomas. The lesions were present in large numbers throughout the animal, most commonly on the external surface of the rumen and reticulum, tongue, peritoneal surface of the gastrointestinal tract, and, less commonly, on the omemtum, flank, and flank muscles. Lesions were also more rarely present on the skin over the ribs, the cheek, or under the jaw. Affected carcasses were condemned. Cases were observed in cattle from different geographical sites in northern and central Queensland, Australia, on seven occasions over a period of more than two years. In one case, up to 30% of a group of 324 cows, between 10–12 yrs old, had lesions. Cases were also reported in three-year-old steers, bulls, and breeding cattle that were in calf. Initially observed on abattoir post-mortem inspection, multiple external lesions were subsequently found on live cattle at breeding properties. Post-mortem, these animals also had multiple internal lesions. The source of the *Propionibacterium australiense* has yet to be determined, although animal-to-animal transmission is thought to be most likely (Forbes-Faulkner et al., 2000).

6. **Propionibacterium avidum** (Eggerth 1935) Moore and Holdeman 1969, 7[AL] ("*Bacteroides avidus*" Eggerth 1935; "*Corynebacterium avidum*" Prévot 1938; "*Mycobacterium avidum*" Krasil'nikov 1949)

a′vi.dum. L. neut. adj. *avidum* greedy, voracious.

Description based on a study of 20 strains including ATCC 25577 by Holdeman et al. (1977) and 23 strains by Cummins and Johnson (1986).

Surface colonies on suitable media are 0.5–1.0 mm at 2–3 d, smooth, entire, circular, and white to light cream color. In general, grows better and gives larger colonies than either *Propionibacterium acnes* or *Propionibacterium granulosum*.

Glucose broth is generally turbid with a smooth abundant sediment which resuspends readily. Generally β-hemolytic on sheep, horse, or rabbit blood agar (19/23 strains; Cummins and Johnson, 1986) which agrees well with the results of Hoeffler (1977) on sheep, human, and rabbit blood agar. A thiol-activated extracellular hemolysin has been partially isolated (Fujimura et al., 1982).

Grows anaerobically or as a microaerophile when freshly isolated, but will often grow well aerobically after a few transfers. Appears to be the best adapted species of the "cutaneous" group for growth in aerobic environments (Cove et al., 1983). Catalase-positive.

Nutritional requirements are less exacting than either *Propionibacterium acnes* or *Propionibacterium granulosum* and, after several transfers, will grow in simple medium consisting of salts, glucose, and vitamins (Ferguson and Cummins, 1978). Pantothenic acid is an absolute requirement for growth.

Peptidoglycan contains alanine, glutamic acid, and glycine amino acid residues. Type I peptidoglycan contains LL-DAP, whereas type II contains *meso*-DAP, but a few strains have LL-DAP and no glycine (thus resembling similar strains of *Propionibacterium acnes* type II). Type I strains contain glucose, galactose, and mannose sugars in their cell wall, while type II contains glucose and mannose only, again resembling type II *Propionibacterium acnes* (Johnson and Cummins, 1972).

Strains are normally positive for gelatinase and deoxyribonuclease; most are negative for lecithinase, hyaluronidase, and chondroitin sulfatase (Hoeffler, 1977).

Source: principally, the moister areas of the skin: e.g., vestibule of the nose, axilla, perineum, and from chronically infected areas such as sinuses and occasionally from abscesses.

DNA G+C content (mol%): 62–63 (T_m).

Type strain: ATCC 25577, CCUG 36754, CIP 103261, DSM 4901, NBRC 15671, NCTC 11864, VPI 179.

Sequence accession no. (16S rRNA gene): AJ003055.

Further comments: member of the "cutaneous" group of propionibacteria. *Propionibacterium avidum* can be divided into two serological groups designated type I and II (Johnson and Cummins, 1972). By DNA–DNA hybridization, sequences within each group were at least 90% similar, but between the two groups the mean similarity was 80% (Goodsell et al., 1991). On the basis of 16S rRNA gene sequence analysis, *Propionibacterium avidum* is most closely related to *Propionibacterium propionicus* but also clusters with *Propionibacterium acnes* (Figure 232). Only two out of 22 type I strains (including the type strain) fermented inositol, in contrast to type II strains which all ferment inositol. *Propionibacterium avidum* has been rarely associated with severe infection after invasive procedures. These include skeletal infection such as sacroiliitis and septic arthritis of the hip (Million et al., 2008) and soft tissue infection such as splenic (Vohra et al., 1998) and breast abscesses (Panagea et al., 2005). The immunostimulatory properties of *Propionibacterium avidum* strain KP-40 have been studied and anti-metastatic activity demonstrated in mice (Isenberg et al., 1994; Isenberg et al., 1995). Previous studies have shown sensitivity to benzylpenicillin, ampicillin, cephalothin, rifampin, clindamycin, erythromycin, and minocycline (Eady et al., 1989). Little information is available on the current susceptibility of *Propionibacterium avidum* strains, but analysis of an isolate responsible for a post-surgical breast abscess revealed sensitivity to penicillin G, ampicillin, erythromycin, tetracycline, and vancomycin and resistance to metronidazole (Panagea et al., 2005). Erythromycin-resistant strains have been isolated from acne patients treated with oral erythromycin and topical clindamycin (Eady et al., 1989).

7. **Propionibacterium cyclohexanicum** Kusano, Yamada, Niwa, Yamasato 1997, 830[VP]

cy.clo.hex.a′ni.cum. Gr. n. *kuklos* circle; Gr. n. *hex* six; L. neut. suff. *-icum* suffix used with the sense of pertaining to; N.L. neut. adj. *cyclohexanicum* relating to ω-cyclohexyl fatty acid, the characteristic cellular fatty acid of the organism.

Description based on the literature description of the type strain TA-12[T] (Kusano et al., 1997; Walker and Phillips, 2007).

After 3 d growth, surface colonies on peptone-yeast extract-glucose (PYG) agar at 35°C in a gas atmosphere of 20% CO_2: less than 0.1% O_2 are circular, white-to-creamy, translucent, and 0.2–0.5 mm in diameter. Optimal growth temperature of 35°C.

Lactic acid is a major product of fermentation in addition to propionic and acetic acids.

Colony formation on plates incubated aerobically. Catalase-negative.

Growth at pH 3.2–7.5; optimum pH 5.5–6.5; can survive up to 90°C in PYG broth and 95°C in orange juice at pH 3.9 for 10 min.

ω-Cyclohexyl undecanoic acid accounts for 52.7% of the total fatty acids. Other fatty acids determined include the straight-chain and anteiso-branched fatty acids n-C_{15} (16.8%), C_{15}, (6.4%), n-C_{16} (2.8%), and n-C_{17} (5.3%).

Peptidoglycan contains alanine, glutamic acid, and *meso*-DAP; whole-cell sugars are galactose, glucose, mannose, ribose, and rhamnose.

Source: spoiled off-flavor pasteurized orange juice.

DNA G+C content (mol%): 66.8 (T_m).

Type strain: TA-12, ATCC 700429, CCUG 48885, CIP 105414, IAM 14535, JCM 21245, NBRC 103082, NRIC 0247.

Sequence accession no. (16S rRNA gene): D82046.

Further comments: on the basis of 16S rRNA gene sequence analysis, *Propionibacterium cyclohexanicum* is most closely related to *Propionibacterium australiense* but also clusters with *Propionibacterium freundenreichii*, the closest of the "classical" propionibacteria (Figure 232). The ω-cyclohexane fatty acids are also found in the cell membranes of *Alicyclobacillus* which is acidophilic and thermotolerant but

does not belong to the *Actinobacteria*, and *Curtobacterium pusillum*. It is the most thermotolerant of the propionibacteria as it can grow and survive in a number of fruit juices; it may therefore survive pasteurization processes used in the fruit juice industry (Kusano et al., 1997; Walker and Phillips, 2007).

8. **Propionibacterium granulosum** (Prévot 1938) Moore and Holdeman 1970, 15[AL] ("*Corynebacterium granulosum*" Prévot 1938)

gra.nu.lo′sum. L. n. *granulum* a small grain; L. neut. suff. -*osum* suffix meaning full of; N.L. neut. adj. *granulosum* full of granules.

Description based largely on a study of the reference strains and 36 other strains by Holdeman et al. and of 30 additional strains originally isolated by Charles Evans, University of Washington, Seattle, and examined by Cummins and Johnson (1986). Surface colonies on suitable media up to 1 mm at 2–3 d, generally white or grayish, smooth, circular, entire, usually larger and more whitish than colonies of *Propionibacterium acnes*. Glucose broth cultures are generally turbid with a rather coarsely granular deposit; often rather viscid and difficult to centrifuge cleanly. Generally nonhemolytic on sheep, horse, or rabbit blood, although reported β-hemolytic on rabbit blood by Hoeffler (1977). Very poor or no growth under aerobic conditions. Catalase-positive. Peptidoglycan amino acid residues are alanine, glutamic acid, glycine, and LL-DAP. Cell-wall sugar components are galactose, mannose, and glucosamine (Johnson and Cummins, 1972). Nutritional requirements are generally the same as *Propionibacterium acnes* requiring pantothenate, although some strains appear to require additional unidentified factors (Ferguson and Cummins, 1978).

Most strains had an active deoxyribonuclease andlecithinase; chondroitin sulfatase, hyaluronidase, and phosphates activity was detected in a few strains, but none produced gelatinase (Hoeffler, 1977). *Propionibacterium granulosum* has a lipase which is considerably more active than that of *Propionibacterium acnes* (Greenman et al., 1981).

Source: sebum-rich oily areas of the skin but in significantly smaller numbers than *Propionibacterium acnes* (McGinley et al., 1978). *Propionibacterium granulosum* is found along with *Propionibacterium acnes* in acne comedones and may play some part in the pathogenesis of acne. It is especially common in the region of the alae nasi (McGinley et al., 1978). The type strains was isolated as a contaminant from a culture labeled *Staphylococcus aerogenes*.

DNA G+C content (mol%): 63 (T_m).

Type strain: ATCC 25564, CCUG 32987, CIP 103262, DSM 20700, LMG 16726, NCTC 11865, VPI 507.

Sequence accession no. (16S rRNA gene): AJ003057.

Further comments: member of the "cutaneous" group of propionibacteria. *Propionibacterium granulosum* seems to have been first separated from *Propionibacterium acnes* (although those names were not used) by Brzin (1964) who recognized a group of strains that did not produce indole or reduce nitrate but could ferment sucrose and maltose. This distinction was later confirmed by Voss (1970) who showed that the indole-negative, nitrate-negative strains were serologically distinct from typical "*acnes*" strains. On the basis of acid extracts containing cell-wall polysaccharide, all strains belong to a single type, with little or no cross-reaction against polysaccharides from *Propionibacterium acnes* or *Propionibacterium avidum* (Cummins, 1975). However, Hoeffler et al. (1977) have found at least three types by tube or slide agglutination of intact suspensions which points to the existence of several surface antigens. Strains of *Propionibacterium granulosum* show low DNA similarity (~12–15%) to both *Propionibacterium acnes* and *Propionibacterium avidum* which is similar to the level of relationship that is found between *Propionibacterium acnes* and the "classical" propionibacteria (Johnson and Cummins, 1972). This is further illustrated by 16S rRNA gene sequence analysis which shows *Propionibacterium granulosum* more closely related to the "classical" propionibacteria than to *Propionibacterium acnes* or *Propionibacterium avidum* (Figure 232). Adjuvent therapy using *Propionibacterium granulosum* strain KP-45 resulted in a significant improvement in the survival of patients with stage I and stage II colorectal cancer (Isenberg et al., 1994). Antibiotic susceptibility studies with a septicemia isolate demonstrated sensitivity to penicillin G, ampicillin, erythromycin, cefotaxime, clindamycin, rifampin, and imipenem, but resistance to metronidazole, sulfonamide, fosfomycin, and tobramycin (Branger et al., 1987). Studies with an isolate responsible for endocarditis revealed susceptibility to penicillin, clindamycin, augmentin, piperacillin, chloramphenicol, cefotaxime, and cefazolin, but resistance to metronidazole (Chaudhry et al., 2000). As with other "cutaneous" propionibacteria, erythromycin-resistant strains of *Propionibacterium granulosum* have been isolated from the skin of acne patients treated with oral erythromycin and topical clindamycin (Eady et al., 1989).

9. **Propionibacterium jensenii** van Niel 1928, 163[AL] ("*Bacterium acidi propionici b*" von Freudenreich and Orla-Jensen 1906; "*Propionibacterium jensenii* var. *raffinosaceum*" van Neil 1928; "*Propionibacterium peterssonii*" van Niel 1928; "*Propionibacterium technicum*" van Niel 1928; "*Propionibacterium raffinosaceum*" Werkman and Kendall 1931; "*Propionibacterium zeae*" Hitchner 1932)

jen.se′ni.i. N.L. gen. masc. n. *jensenii* of Jensen; named for Sigurd Orla-Jensen (1870–1949), the Danish bacteriologist who first isolated this organism.

Description based on literature descriptions, including those of Werkman and Brown (1933), Sakaguchi et al. (1941), and Janoschek (1944) and on the study of 13 strains including 3 of *Propionibacterium jensenii* [ATCC 4867 (van Neil 24), ATCC 4868 (van Neil 29), and ATCC 4869 (van Neil 1)]; 2 of "*Propionibacterium technicum*" [ATCC 14073 (van Neil E.6.1) and ISL 106 (van Neil 22)]; 1 of "*Propionibacterium raffinosaceu*" [ISL 103 (van Neil 29)]; 1 of "*Propionibacterium peterssoni*" [ATCC 4870 (van Neil 20)]; 1 of "*Propionibacterium zeae*" [(ATCC 4964 (Hitchner)]; and ATCC 4871. Phenotypic characteristics of these strains are similar to original descriptions of *Propionibacterium jensenii*, "*Propionibacterium raffinosaceum*", "*Propionibacterium technicum*", "*Propionibacterium peterssonii*", or "*Propionibacterium zeae*".

Surface colonies on horse blood agar (2 d) are punctiform, circular, entire, convex, glistening, semiopaque, and white, cream, or pink. Colonies in deep agar are 4 mm or less, lenticular and white, pink or red-brown.

Glucose broth cultures are turbid or clear with smooth, granular or ropy sediment and terminal pH of 4.4–4.9.

Only strains producing the red polyene pigment granadaene have been shown to be hemolytic (Vedamuthu et al., 1971). Twenty pigmented strains produced β-hemolytic activity on horse blood agar. The hemolytic system of *Propionibacterium jensii* appears similar to that of *Streptococcus agalactiae* (Vanberg et al., 2007).

Some strains grow as well aerobically as anaerobically. Variable catalase activity.

Requires pantothenate and biotin for growth. Some require *p*-aminobenzoic acid while for others it is stimulatory. Thiamine is also stimulatory but not essential (Delwiche, 1949).

Peptidoglycan contains alanine, glutamic acid, glycine, and LL-DAP as diamino acid; cell-wall sugars are glucose and galactose, usually with small amounts of mannose.

Source: dairy products and silage.

DNA G+C content (mol%): 65–68 (T_m).

Type strain: ATCC 4868, CCUG 48883, CIP 103028, DSM 20535.

Sequence accession no. (16S rRNA gene): AJ704571, X53219.

Further comments: member of the "classical" or "dairy" group of propionibacteria. On the basis of 16S rRNA gene sequence analysis, *Propionibacterium jensenii* clusters with *Propionibacterium thoenii* (Figure 232). Some preliminary data suggest that the *Propionibacterium jensenii* strain PJ702 may have application as a living vaccine vector for tuberculosis and other mucosally transmitted diseases (Adams et al., 2005).

10. **Propionibacterium microaerophilum** Koussémon, Combet-Blanc, Patel, Cayol, Thomas, Garcia and Ollivier 2001, 1380^VP

mi.cro.a.e.ro′phi.lum. Gr. adj. *mikros* small, Gr. n. *aer* air; Gr. adj. *philos -ê -on* loving; N.L. neut. adj. *microaerophilum* slightly air-loving.

Description based on the literature description of the type strain M5^T (Koussémon et al., 2001).

Surface colonies on yeast extract minimal salts basal medium (YEM; prepared and stored using oxygen-free nitrogen) agar prepared under microaerophilic conditions (95:5% N_2/O_2) at 30°C are white after 1 week and lens-shaped with smooth edges and 2–3 mm in diameter.

Growth pH range 4.5–9.5; optimum 7.0. Mesophilic, with an optimum growth temperature of 30°C; range 20–45°C. Killing was observed at 80°C.

Growth occurs under anaerobic and aerobic conditions with an optimum O_2 concentration of 5% in the gas phase of the culture. Catalase-negative. Nitrate is reduced to nitrogen rather than nitrite.

The type strain M5 does not require growth factors such as pantothenate, biotin, or thiamin and is, therefore, prototrophic. This is in contrast to other propionibacteria which display auxotrophic behavior.

Source: decantation reservoir of olive mill wastewater.

DNA G+C content (mol%): 67.7 (T_m).

Type strain: M5, CNCM I-2360, DSM13435.

Sequence accession no. (16S rRNA gene): AJ234623.

Further comments: on the basis of 16S rRNA gene sequence analysis, *Propionibacterium microaerophilum* clusters with the "classical" propionibacteria and is most closely related to *Propionibacterium acidipropionici* (97.5% similarity) (Figure 232). Despite this, DNA–DNA hybridization experiments with *Propionibacterium acidipropionici* DSM 4900 only showed a reassociation value of 56.2%. Originally isolated from a decantation reservoir of olive mill wastewater that is stored to enable natural bioremediation prior to river disposal. Isolated by enrichment in deep minimal salts glucose basal medium agar (0.6 g KH_2PO_4, 0.2 g $MgCl_2 \cdot 6H_2O$, 1 g NH_2%Cl, 1 g NaCl, and 10 ml trace-element solution supplemented with 0.1 g yeast extract L <MIN>1 and 10 mM glucose) prepared under anaerobic conditions (Koussémon et al., 2001). This species is unlike other members of the genus as growth is sustained on a minimal salts glucose medium with ammonium salts as the only nitrogen source, although yeast extract enhances growth.

11. **Propionibacterium propionicum** corrig. (Buchanan and Pine 1962) Charfreitag, Collins and Stackebrandt 1988, 357^VP ("*Actinomyces propionicus*" Buchanan and Pine 1962)

pro.pio′ni.cum. N.L. n. *acidum propionicum* propionic acid; N.L. neut. adj. *propionicum* pertaining to propionic acid.

Previously *Actinomyces propionicus* (Buchanan and Pine, 1962) and *Arachnia propionica* (Pine and Georg, 1969; Schaal, 1986). Original spelling of the specific epithet, "propionicus" was corrected by Moore and Moore (1992).

Short irregular rods, 0.2–0.3 µm in diameter and 3–5 µm long, which may or may not be branched, as well as slender branching filaments 5–20 µm in length or longer (Figure 236). These filaments are especially evident in young liquid media cultures but commonly break up in older cultures into short rods (Figure 237). Rods are of variable length, often with clubbed ends and are commonly arranged in pairs, in Y or V configurations, or in parallel rows forming palisades. Gram stain may be uneven, with a beaded appearance. Swollen spherical cells resembling sphaeroplasts, up to 5–20 µm in diameter, are formed by some strains.

Cellular morphology varies with sugar substrate and growth conditions. Colony appearance may be variable; off-white to buff, breadcrumb, gritty, pitting or smooth, convex, entire edged. Young microcolonies are commonly composed of tangled filaments; older colonies may be heaped or convoluted with an undulant edge. Both types (rough and smooth) may occur together. Microscopically, colonies are mycelial with long hyphal branched elements but with no aerial filaments and can resemble *Actinomyces israelii.* Red fluorescence observed under ultraviolet light (365 nm) on blood agar.

Hemolytic on human blood agar, variable hemolysis on horse blood agar, and non-hemolytic on sheep blood agar.

Grows in pure culture both aerobically and anaerobically. Increased CO_2 is reported as a requirement for growth

anaerobically and to enhance growth aerobically by Schofield and Schaal (1981) whereas Buchanan and Pine (1962) report that CO_2 does not stimulate growth in broth culture. Obligately anaerobic and slow-growing on primary isolation from clinical samples, requiring up to 14 d incubation (Hall, 2006). Catalase-negative.

Peptidoglycan contains LL-DAP as the dibasic amino acid. Two distinct cell-wall sugar patterns have been described. Strains contain essentially only galactose or galactose and glucose with trace amounts of mannose, but not rhamnose or 6-deoxylatose.

Little or no proteloytic activity. API tests for hyaluronidase, esterase (C_4), esterase lipase (C_8), leucine arylamidase, and α-glucosidase are positive for all or the majority of isolates. Alkaline and acid phophatases, lipase (C_{14}), valine and cystine arylamidase, phosphoamidase, β-glucouronidase, β-glucosidase, α-mannosidase, and α-fucosidase are negative. Chymotrypsin, α-galactosidase, β-galactosidase, and *N*-acetyl-β-glucosamine are variable with ~10–50% isolates positive (Kilian, 1978; Schofield and Schaal, 1981).

Source: isolated from the oral cavity of humans including the mucosa, tonsils, and dental plaque, occasionally isolated from the gastrointestinal tract and female genital tract. It seems unlikely to represent part of the indigeous microbiotia. It may also be present in the oral cavity of other animals (Bowden, 1991). Isolated from lacrimal canaliculitis (inflammation of the short passage which drains tears form the lacrimal lake to the lacrimal sac).

DNA G+C content (mol%): 63–65 mol% (T_m).

Type strain: ATCC 14157, CCUG 4939, CIP 101941, DSM 43307, JCM 5830, NBRC 14587, NCTC 12967, VKM Ac-1449.

Sequence accession no. (16S rRNA gene): AJ003058, AJ315953, X53216.

Further comments: description based largely on the reference strain and eight other strains (Buchanan and Pine, 1962; Charfreitag et al., 1988; Cummins and Moss, 1990; Johnson and Cummins, 1972; Schofield and Schaal, 1981) and numerous clinical isolates (Hall, 2006). Two distinct serovars, based on fluorescent antibody labeling, have been described: serovar 1 (type strain ATCC 14157) and 2 (ATCC 29326, WVU† 346, F. Lentze strain "Fleischmann": VPI5067, CDCW904; isolated from a typical case of human actinomycosis in Germany), (Gerencser and Slack, 1967; Holmberg and Forsum, 1973). These serotypes also form separate clusters on numerical phenetic analysis (Schofield and Schaal, 1981). To date, there is no published information relating to any phylogenetic differences.

On the basis of 16S rRNA gene sequence analysis, *Propionibacterium propionicum* clusters with *Propionibacterium avidum* (Figure 232). Microscopically, the bacterium can be mistaken for *Streptococcus* species in clinical material as it can form chains of cells with coccoid appearance. Recognized cause of actinomycosis, a chronic granulomatous disease which commonly affects the cervicofacial area but may also cause infection of, for example, the thorax, abdomen, or pelvis. The organism is sometimes associated with the use of intra-uterine contraceptive devices. (Hall, 2006). Most commonly associated with infections of the lacrimal apparatus such as lacrimal canaliculitis (Brazier and Hall, 1993). It is not possible to clinically distinguish between *Actinomyces* species and *Propionibacterium propionicum* as the underlying cause of these diseases. *Propionibacterium propionicum* is morphologically similar to *Actinomyces israelii* but a distinguishing feature is propionic acid production from glucose metabolism. Long-term, high dose antibiotic therapy is frequently necessary; late diagnosis and insufficient treatment can lead to fatality (Hall, 2006). *Propionibacterium propionicum* is also associated with primary and persistent ondodontic infection (Siqueira and Rocas, 2003). Johnson and Cummins (1972) describe VPI 5077 as an unidentifiable isolate with 1% DNA similarity to ATCC 14157 (Type 1 *Propionibacterium propionicum*) and no antigenic cross-reactivity, received in their laboratory as "*Arachnia propoionica*". In the results, this isolate is listed as VPI 5067, a synonym for ATCC 29326: WVU 346 (F Lentz strain "Fleishman") reported by Gerencser and Slack (1967) as Type 2 "*Actinomyces propionicus*". Subsequent publications have quoted the results obtained by Johnson and Cummins (1972) as relating to VPI 5067. It is not known if the tabular designation VPI5067 in Johnson and Cummins (1972) is an error. Most isolates are sensitive to a wide selection of antibiotics including penicillins, erythromycin, clindamycin, imipenem cephalosporins, chloramphenicol, and tetracyclines. Resistant to metronidazole, fluoroquinolones, aztreonam, and aminoglycosides.

12. **Propionibacterium thoenii** van Niel 1928, 164[AL] ("*Bacterium acidi propionici* var. *rubrum*" Thöni and Allemann 1910; "*Propionibacterium rubrum*" van Niel 1928)

tho.e′ni.i. N.L. gen. masc. n. *thoenii* of Thöni; named for J. Thöni, the Swedish bacteriologist who first isolated this organism.

Description based on a study of the type strain and ATCC 4871 ("*Propionibacterium rubrum*" van Niel 23) and ATCC 4872 ("*Propionibacterium rubrum*" van Niel 19).

Surface colonies at 4 d are circular, entire, smooth, and generally orange or red-brown.

Broth cultures show generalized turbidity with brownish-red or orange-red deposit; terminal pH in glucose broth is 4.7–4.9.

Shows β-hemolysis on blood agar containing human, bovine, equine, sheep, rabbit or pig blood.

Less strictly anaerobic than the type species (van Niel, 1957). Catalase-positive.

Pantothenate and biotin are essential for growth. Thiamine is required by some strains and is stimulatory to others, while *p*-aminobenzoic acid is not required (Delwiche, 1949).

Peptidoglycan contains alanine, glutamic acid, glycine, and LL-DAP as diamino acid, and cell-wall sugars are glucose and galactose.

Source: originally isolated from red spots in Emmentaler cheese (Thöni and Alleman, 1910), also found in other dairy products.

DNA G+C content (mol%): 66–67 (T_m).

Type strain: ATCC 4874, CCUG 28149, CIP 103029, DSM 20276, HAMBI 247, JCM 6437, LMG 16455.

Sequence accession no. (16S rRNA gene): AJ704572, X53220.

Further comments: member of the "classical" or "dairy" group of propionibacteria. On the basis of 16S rRNA gene sequence analysis, *Propionibacterium thoenii* clusters with *Propionibacterium jensenii* (Figure 232). It has been recognized for some time that the strains described under the names *Propionibacterium thoenii* and "*Propionibacterium rubrum*" have many features in common, not least the production of an intense red or reddish brown pigment. The nature of the pigment is not known. Classically, (van Niel, 1957) "*Propionibacterium rubrum*" ferments raffinose and mannitol but not sorbitol, while *Propionibacterium thoenii* ferments sorbitol, but not raffinose or mannitol. However, strains of *Propionibacterium thoenii* and "*Propionibacterium rubrum*" show high DNA similarity (Johnson and Cummins, 1972) and, therefore, it was recommended that they be combined in a single species. Sequence comparison of the complete 16S rRNA genes revealed only 12 bp differences thus confirming the similarity (de Carvalho et al., 1995). Some strains of *Propionibacterium thoenii* have been shown to produce bacteriocins under different growth conditions (Ben-Shushan et al., 2003; Van der Merwe et al., 2004).

Genus II. **Aestuariimicrobium** Jung, Kim, Song, Lee, Oh and Yoon 2007, 2117[VP]

Susmitha Seshadri

A.es.tu.a.ri.i.mi.cro′bi.u.m. L. n. *aesturarium* part of the sea coast which, during the flood-tide, is overflowed, but at the ebb-tide is left covered with mud or slime, a tidal flat; N.L. neut. n. *microbium* microbe; N.L. neut. n. *Aestuariimicrobium* a microbe isolated from a tidal flat.

Short to coccoid nonsporeforming rods. Cells are nonflagellated and stain **Gram-positive**. **Aerobic**. Growth occurs between 4–40°C with **30°C as the optimal temperature**. The optimal pH range for growth is 7.5–8.5. Colonies are pigmented yellow. Nitrate is reduced to nitrite. **Catalase-positive**. The major **menaquinone is MK-9(H_4)** and the **predominant fatty acid is $C_{15:0}$ antesio**.

DNA G+C content (mol%): 68.8–69.2.

Type species: **Aestuariimicrobium kwangyangense** Jung, Kim, Song, Lee, Oh and Yoon 2007, 2117[VP].

Further descriptive information

The only species in this genus was isolated from an oil contaminated tidal flat sediment by enrichment with diesel oil and exhibits diesel oil degradation activity. Phylogenetic studies based upon the 16S rRNA indicate that *Aestuariimicrobium* is closely affiliated to the family *Propionibacteriaceae*. On the basis of phylogenetic, phenotypic, chemotaxonomic and genetic studies, *Aestuariimicrobium* is classified as a novel genus. Cell wall contains LL-diaminopimelic acid.

Enrichment and isolation procedures. Isolation was performed by inoculating 0.5 mg of the oil-contaminated sediment samples in 100 ml of Bushnell–Haas broth with 2% (w/v) diesel oil. Cultures were incubated at 30°C on a horizontal shaker at 150 r.p.m. Four strains R27^T, R44, R45, and R47 with diesel oil degradation activity were isolated by dilution plating on R2A agar.

Maintenance procedures

Routine subculturing is done on R2A agar at 30°C. Can be cultivated in R2A broth without the agar, supplemented with 2% (v/v) Hutner's mineral base and 0.1% (v/v) trace element solution.

Differentiation of the genus *Aestuariimicrobium* from closely related genera

The almost-complete 1472 nucleotide long 16S rRNA gene sequence of the four isolated strains showed low sequence similarity to other genera in the family *Propionibacteriaceae* and form a distinct lineage. *Aestuarimicrobium* is aerobic in comparison to phylogenetically closely related genera such as *Propionibacterium*, *Propioniferax*, *Tessaracoccus* and *Luteococcus*, which are all facultative anaerobes. The four above-mentioned genera differ from *Aestuariimicrobium* in one or more of phenotypic properties such as their shape, temperature and pH requirements for growth, catalase production, and nitrate reduction. *Aestuariimicrobium* and *Tessaracoccus* both contain only $C_{15:0}$ antesio as the major fatty acid while the other genera contain more than one major fatty acid. *Tessaracoccus* contains both MK-9(H_4) and MK-7(H_4) while *Aestuariimicrobium* contains only MK-9(H_4) as the predominant menaquinone.

List of species of the genus *Aestuariimicrobium*

1. **Aestuariimicrobium kwangyangense** Jung, Kim, Song, Lee, Oh and Yoon 2007, 2117[VP]

kwang.yang.en′se. N.L. neut. adj. *kwangyangense* of or belonging to Kwangyang, Korea, the source of isolation.

Cells are short rods or cocci (0.6–1.2 × 1.2–2.0 μm). Colonies measure 0.8–1.0 mm after 3 d of growth at 30°C on R2A agar. Colonies are circular, convex, smooth and yellow in color. No growth occurs anaerobically with or without nitrate supplementation on R2A agar. Esculin, casein and Tweens 20, 40, 60, and 80 are hydrolyzed, while starch, hypoxanthine, xanthine and tyrosine are not. D-Glucose, D-fructose, D-galactose, D-cellobiose, D-mannose, D-xylose, sucrose, maltose and salicin, are utilized as sole carbon and energy sources, but L-arabinose, acetate, citrate, succinate, L-malate, formate and L-glutamate are not utilized. Utilization of trehalose, benzoate, and pyruvate are variable. Susceptible to penicillin G, chloramphenicol, ampicillin, cephalothin, novobiocin, tetracycline and carbenicillin, but not to polymyxin B, streptomycin, gentamicin, kanamycin, lincomycin, oleandomycin or neomycin. The API ZYM system detects the presence of esterase (C4), esterase lipase

(C8), leucine, arylamidase, acid phosphatase, α-galactosidase, β-galactosidase, α-glucosidase and β-glucosidase but not alkaline phosphatase, lipase (C14), valine arylamidase, cystine arylamidase, trypsin, α-chymotrypsin, *N*-acetyl-β-glucosaminidase, α-mannosidase and α-fucosidase. Naphthol-AS-BI-phosphohydrolase and β -glucuronidase activities are negative for the type strain, but other strains are positive.

DNA G+C content (mol%): 68.8–69.2 (HPLC).

Type strain: R27, KCTC 19182, JCM 14204.

Sequence accession no. (16S rRNA gene): DQ830982.1.

Genus III. **Brooklawnia** Rainey, da Costa and Moe 2006, 1981[VP] (*in* Bae, Moe, Yan, Tiago, da Costa and Rainey 2006b)

Milton S. da Costa, Fred A. Rainey and William M. Moe

Brook.law′ni.a N.L. fem. n. *Brooklawnia* named after Brooklawn, the contaminated site from which members of the genus were first isolated.

Pleomorphic rods. Colonies are white. Nonsporeforming. Gram-stain-positive. Strains are **nonmotile**. **Mesophilic** with a temperature optimum for growth of about 37°C; neutrophilic with an optimum pH for growth of about 6.5. **Menaquinone 9(H_4)** is the predominant respiratory quinone. Fatty acids are primarily **iso-** and **anteiso-branched**; straight-chain fatty acids are also present. Cell-wall peptidoglycan contains *meso*-DAP (A1γ). Cells are catalase-positive and oxidase-negative, and nitrate is not reduced. **Facultatively anaerobic**. **Chemoheterotrophic**. Propionate and acetate are the predominant products of glucose fermentation. Strains of this genus were isolated from groundwater contaminated with chlorosolvents.

DNA G+C content (mol%): 67.5–67.9.

Type species: **Brooklawnia cerclae** Rainey, da Costa and Moe 2006, 1981[VP] (*in* Bae, Moe, Yan, Tiago, da Costa and Rainey 2006b).

Further descriptive information

One species, *Brooklawnia cerclae*, is currently classified in this genus (Bae et al., 2006b). The isolates of this species form colorless colonies that are about 1–3 mm in diameter under anaerobic growth conditions. The organisms are able to grow under aerobic and anaerobic conditions, but growth is better under an atmosphere of H_2 (10%), CO_2 (10%), and N_2 (80%) or under CO_2 (5%) and N_2 (95%).

Strains BL-34[T] and BL-35 are chemoheterotrophic, growing on a variety of complex media, namely Plate count Agar, Colombia Anaerobic Sheep Blood, and Peptone/Yeast Extract/Glucose (PYG) medium. Several carbon sources are assimilated, among them carbohydrates, organic acids, and methanol. The major fermentation products of glucose fermentation are propionate and acetate.

Iso-and anteiso-branched fatty acids are the major fatty acids; $C_{15:0}$ anteiso, and C_{15} iso account for about 84–86% of the total, which is much higher than in other closely related species classified in other genera (Bae et al., 2006b). The major respiratory quinone is MK-9(H_4) like those of other closely related organisms. Strains BL-34[T] and BL-35 are not able to assimilate or transform 1,2-dichloroethane (1,2-DCA) or 1,1,2-trichloroethane (1,1,2-TCA) despite being isolated from water containing high levels of these chlorosolvents. However, they are extremely resistant to these solvents and able to grow in media with solvent concentrations of up to 9.8 mM. The resistance to chlorosolvents may explain their ability to colonize and their subsequent isolation from the Brooklawn site where petrochemicals were disposed and where 1,1,2,2-tetrachloroethane, 1,1,2-trichloroethane, 1,2-dichloroethane, 1,2-dichloropropane, hexachloro-1,3-butadiene, hexachlorobenzene, vinyl chloride, and polycyclic aromatic hydrocarbons (PAHs) are present in ground water in large quantities (Clement et al., 2002; US EPA, 2005). Another organism isolated from this site, *Propionicicella superfundia* (Bae et al., 2006c), also tolerated high levels of chlorosolvents, but was not able to transform them.

Enrichment, isolation, and growth conditions. The isolates of *Brooklawnia cerclae* were recovered from ground water at the Brooklawn Site (Petro-Processors of Louisiana, Inc. Superfund Site) located near Baton Rouge, LA (USA). Strain BL-34[T] was isolated on Nutrient Agar (Difco) supplemented with 0.5 g/l, L-cysteine, 1.0 mg/l, and resazurin, adjusted to pH 7.0 prior to autoclaving. Incubation was at 30°C in an anaerobic chamber containing a gas mixture of 10% H_2, 10% CO_2, and 80% N_2 (by vol.). Strain BL-35 was isolated on Plate Count Agar (Difco) supplemented with the same amendments and incubated under the same conditions. The strains are maintained on Colombia Anaerobic Sheep Blood agar plates (BBL) or PYG agar plates (Akasaka et al., 2003b).

Maintenance procedures

The strains are maintained on Colombia Anaerobic Sheep Blood agar plates (BBL) or PYG agar plates (Akasaka et al., 2003b). Strains have been successfully maintained long-term in nutrient broth containing 15% (v/v) glycerol at −80°C.

Taxonomic comments

The genus *Brooklawnia* belongs to the family *Propionibacteriaceae* (Delwiche 1957; Stackebrandt et al. 1997) within the order *Propionibacteriales* (formerly suborder *Propionibacterineae*; Stackebrandt et al., 1997), sharing several characteristics with the species of the most closely related genera. The genera that fall within the radiation of the family *Propionibacteriaceae* include *Propionibacterium* Orla-Jensen 1909, *Aestuariimicrobium* Jung et al. 2007, *Friedmanniella* Schumann et al. 1997, *Granulicoccus* Maszenan et al. 2007, *Luteococcus* Tamura et al. 1994, *Microlunatus* Nakamura et al. 1995, *Micropruina* Shintani et al. 2000, *Propioniferax* Yokota et al. 1994, *Propionicicella* Bae et al. 2006c, *Propionicimonas* Akasaka et al. 2003b, *Propionimicrobium* Stackebrandt et al. 2002, and *Tessaracoccus* Maszenan et al. 1999b. The characteristics that can be used to differentiate *Brooklawnia* from the other genera of the family *Propionibacteriaceae* are shown in Table 206. *Brooklawnia* can be differentiated from *Propionimicrobium* (its closest phylogenetic relative based on branching – see

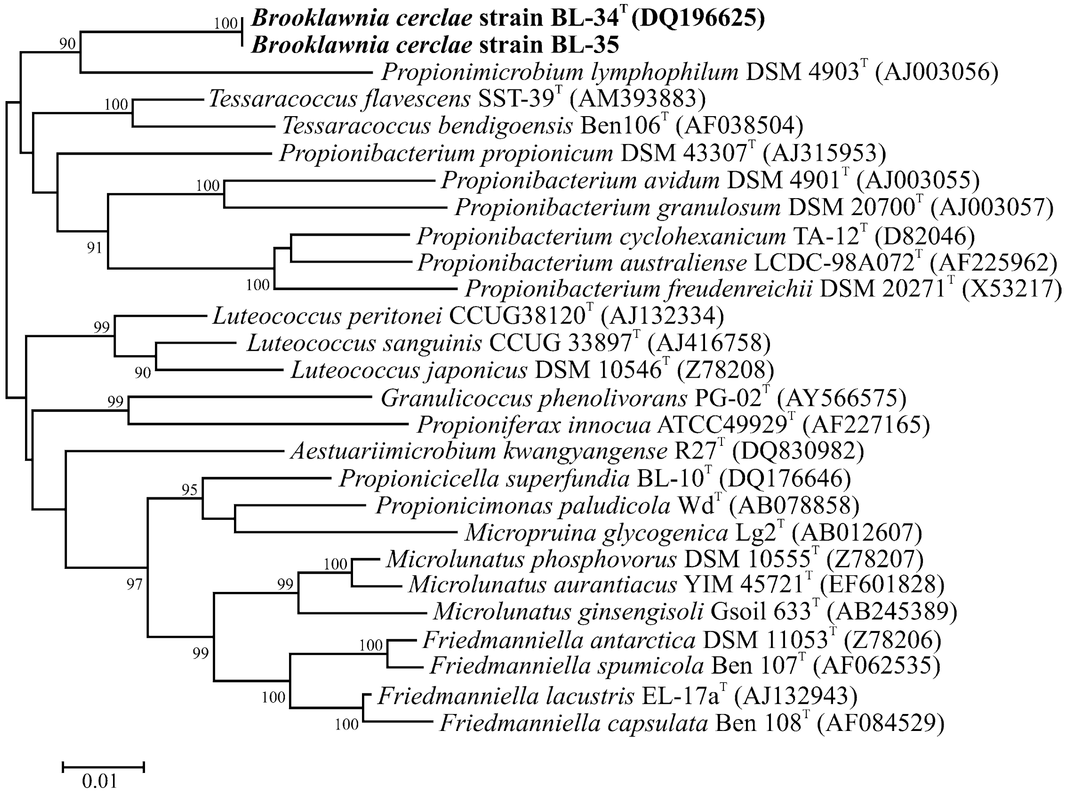

FIGURE 238. 16S rRNA gene sequence based phylogeny indicating the relationship of the genus *Brooklawnia* to other taxa of the family *Propionibacteriaceae*. The scale bar = 1 inferred nucleotide substitution per 100 nucleotides.

Figure 238) on the basis of its cell-wall type and G+C content of the genomic DNA. Differentiation from other genera is, in many cases, based on a combination of chemotaxonomic, physiological, and genomic characteristics (Table 206).

The species *Brooklawnia cerclae* is shown by 16S rRNA gene sequence comparisons to fall within the radiation of the species of the genera of the family *Propionibacteriaceae* (Figure 238). Pairwise sequence similarity values between the 16S rRNA gene sequence of *Brooklawnia cerclae* (DQ196625) and species within the family *Propionibacteriaceae* are in the range 93.5–95.6%. The highest pairwise similarities are to species of the genera *Tessaracoccus* and *Luteococcus* which have short branches as shown in Figure 238. *Brooklawnia cerclae* actually branches with *Propionimicrobium lymphophilum* although the branching is only supported by a bootstrap value of 90%.

List of species of the genus *Brooklawnia*

1. **Brooklawnia cerclae** Rainey, da Costa and Moe 2006, 1981[VP] (*in* Bae, Moe, Yan, Tiago, da Costa and Rainey 2006b)

cer′cla.e. N.L. gen. fem. n. *cerclae* of CERCLA, arbitrary name formed from CERCLA, acronym for Comprehensive Environmental Response, Compensation, and Liability Act, which has mandated cleanup of many hazardous waste sites in the United States.

Cells are Gram-stain-positive, nonmotile, nonspore-forming, pleomorphic rods. Growth occurs at 10°C–40°C; the optimum growth temperature is about 37°C. Growth occurs at pH 4.5–8.0; the optimum pH for growth is 6.5. Growth is not stimulated by addition of NaCl, but is sustained in the presence of up to 3% NaCl (v/v). Facultative anaerobic growth is supported by fermentation. Propionate and acetate are the main products of glucose fermentation. Chemotaxonomic features are the same as the genus description. Growth occurs on arabinose, fructose, glucose, galactose, maltose, rhamnose, xylose, ribose, mannose, starch, glycogen, glycerol, mannitol, lactate, and pyruvate, but not on acetate, ribitol, cellobiose, cellulose, galactitol, erythritol, ethanol, fucose, fumarate, inositol, lactose, malate, methanol, raffinose, sorbitol, succinate, sucrose, or xylan. Strains of this species have been isolated from chlorosolvent-contaminated ground water. Strain BL-35 (LMG 23249, NRRL B-41419) also belongs to this species.

DNA G+C content (mol%) of the type strain: 67.5 (HPLC).

Type strain: BL-34, JCM 14918, LMG 23248, NRRL B-41418.

Sequence accession no. (16S rRNA gene): DQ196625.

Genus IV. **Friedmanniella** Schumann, Prauser, Rainey, Stackebrandt and Hirsch 1997, 282[VP]

Peter Schumann and Rüdiger Pukall

Fri.ed.man.ni.el′la. N.L. fem. dim. n. *Friedmanniella* named after E. Imre Friedmann (1921–2007), an American microbiologist, in recognition of his contributions to Antarctic microbiology.

Spherical to ellipsoidal cells that occur mostly in more or less regular packets which develop through cell division in three perpendicular planes. The packets aggregate, forming clusters. **Gram-stain-positive**. **Nonmotile**. Nonsporeforming. Non-acid-fast. **Strictly aerobic**. **Oxidase-negative**. **Catalase-positive**. Chemo-organotrophic. Only a few carbohydrates, organic acids, and other carbon sources are metabolized. The **peptidoglycan type** is **A3γ** containing **LL-diaminopimelic acid**, glycine in position 1 of the peptide subunit, and a single glycine residue as interpeptide bridge. The major **menaquinone** is **MK-9(H_4)**, and the main **fatty acids** are 12- and 13-methyltetradecanoic acid (**$C_{15:0}$ anteiso and $C_{15:0}$ iso**). Mycolic acids are absent. The **phospholipid pattern** includes **phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol**, and one unknown phospholipid.

Phylogenetically, this genus is affiliated to the family *Propionibacteriaceae* Delwiche 1957, emend. Rainey, Ward-Rainey and Stackebrandt 1997 of the order *Propionibacteriales* Zhi et al. 2009.

DNA G+C content (mol%): 69–74.

Type species: **Friedmanniella antarctica** Schumann, Prauser, Rainey, Stackebrandt and Hirsch 1997, 282[VP].

Further descriptive information

The four species of the genus *Friedmanniella*, *Friedmanniella antarctica* (Schumann et al., 1997), *Friedmanniella capsulata* (Maszenan et al., 1999a), *Friedmanniella lacustris* (Lawson et al., 2000a, 2000b) and *Friedmanniella spumicola* (Maszenan et al., 1999a), form a distinct cluster together with the members of the genera *Microlunatus* (Nakamura et al., 1995), *Micropruina* (Shintani et al., 2000), *Propionicicella* (Bae et al., 2006c), and *Propionicimonas* (Akasaka et al., 2003b) within the phylogenetic tree based on 16S rRNA gene sequences of the suborder *Propionibacterinae* (Figure 239). However, the affiliation of these genera to a family is the subject of conflicting taxonomic opinions (Garrity et al., 2007; Stackebrandt and Schaal, 2006b). For

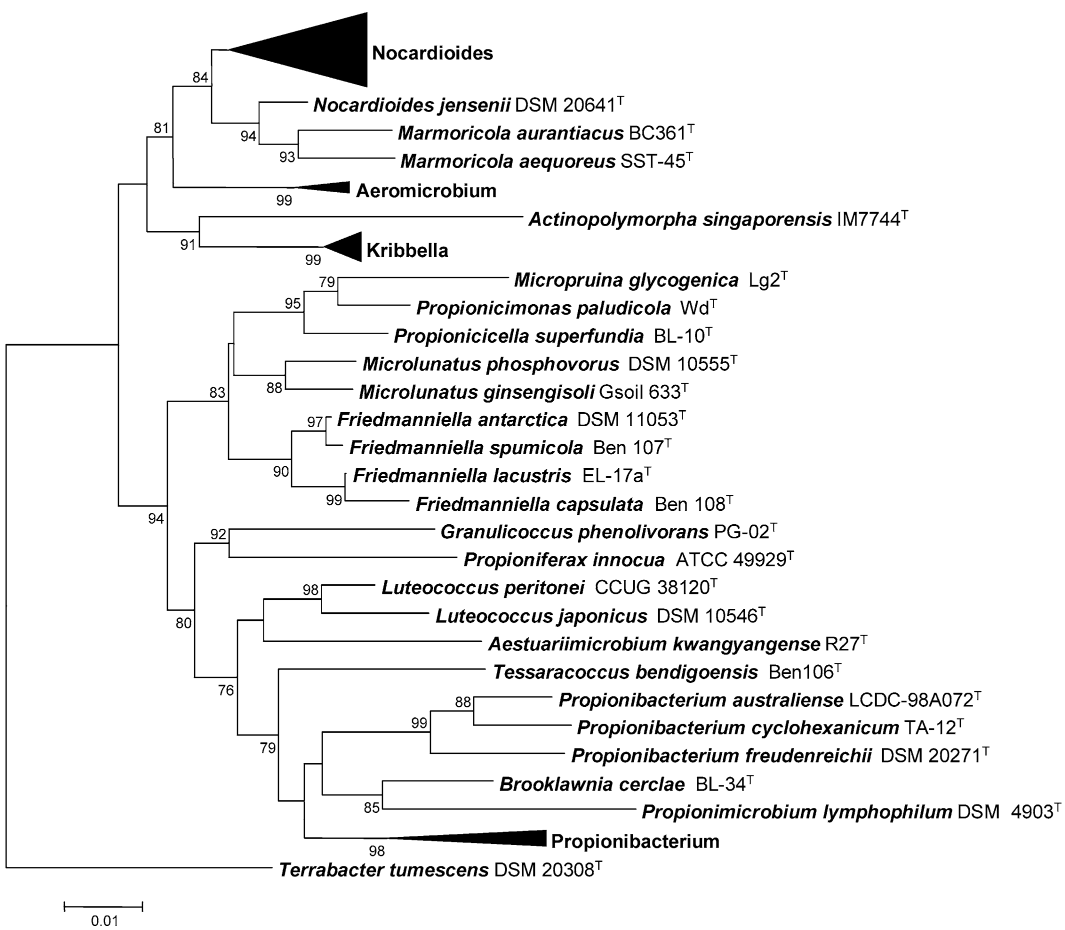

FIGURE 239. Neighbor joining analysis of almost complete 16S rRNA gene sequences from type strains of the genus *Friedmanniella* and other representatives of the *Actinobacteria*. The phylogenetic tree was conducted using Mega 3.1 (Kumar et al., 2004). The Kimura-2-parameter method was used for correction (Kimura, 1980). Bootstrap values were calculated from 1000 resamplings, but values >70% are indicated at branching points only. Bar = 1 subsitution per 100 nucleotides.

reasons given in *Taxonomic comments*, the genus *Friedmanniella* is considered a member of the family *Propionibacteriaceae* in this chapter. The type species with the highest 16S rRNA gene sequence similarity to *Friedmanniella antarctica* are *Microlunatus phosphovorus* (Nakamura et al., 1995), *Propionicicella superfundia* (Bae et al., 2006c), *Propionicimonas paludicola* (Akasaka et al., 2003b), *Aestuariimicrobium kwangyangense* (Jung et al., 2007), *Micropruina glycogenica* (Shintani et al., 2000), and *Brooklawnia cerclae* (Bae et al., 2006b) with values of 94.6%, 94.1%, 94.1%, 93.9%, 93.5%, and 93.6%, respectively. The type species *Friedmanniella antarctica* shows 16S rRNA gene sequence similarity values of 98.8%, 97.3%, and 96.5% to *Friedmanniella spumicola*, *Friedmanniella lacustris*, and *Friedmanniella capsulata*, respectively (all binary 16S rRNA gene sequence similarity values were calculated by the EzTaxon server, Chun et al., 2007). The DNA–DNA similarity values of type strains of *Friedmanniella spumicola* and *Friedmanniella capsulata* to *Friedmanniella antarctica* are 50% and 27%, respectively. *Friedmanniella spumicola* and *Friedmanniella capsulata* are related by more than 97% 16S rRNA gene sequence similarity but show only 29% DNA–DNA similarity (Maszenan et al., 1999a).

Members of the genus *Friedmanniella* are Gram-stain-positive, nonmotile cocci (usually 1.2–1.5 µm in diameter) or cells of nearly spherical shape which show a pronounced tendency to aggregate in clusters of packets which result from cell divisions in three perpendicular planes. The clusters are surrounded and internally subdivided by an extracellular capsular polymer (Maszenan et al., 1999a). Well-developed colonies are pigmented in shades of orange which may become more intense under the influence of light (Schumann et al., 1997). Ageing colonies change in color from orange to faint yellow.

The development of colonies of *Friedmanniella* strains on all tested agar media is usually slow and takes several days or up to 3 weeks. Growth in submerged shaking and standing cultures is often poor. *Friedmanniella lacustris* requires the vitamins biotin, thiamine, and nicotinic acid and grows optimally with 4% (w/v) NaCl. Medium PYGV (DSMZ medium 621; Staley, 1968) supplemented with artificial sea water and vitamins is recommended for cultivation of *Friedmanniella lacustris*. The details for preparation of this medium are given by Stackebrandt and Schaal (2006b). R-Medium (Yamada and Komagata, 1972) or modified organic medium 79 [containing per liter distilled water 10 g glucose, 10 g bacto peptone (Difco), 2 g Casamino acids (Difco), 2 g yeast extract (Serva), 6 g NaCl, and 15 g agar, pH 7.5] can be recommended for the cultivation of *Friedmanniella antarctica*. R2A agar [DSMZ medium 830, containing per liter distilled water 0.50 g yeast extract, 0.50 g proteose peptone (Difco no. 3), 0.50 g Casamino acids (Difco), 0.50 g glucose, 0.50 g soluble starch, 0.30 g Na pyruvate, 0.30 g K_2HPO_4, 0.05 g $MgSO_4 \cdot 7H_2O$, 15.00 g agar – adjust to pH 7.2 with crystalline K_2HPO_4 or KH_2PO_4 before adding agar] is suited for the cultivation of *Friedmanniella capsulata* and *Friedmanniella spumicola*.

Biochemical and physiological characteristics are given in the species descriptions and in Table 207. *Friedmanniella* strains are capable of polyphosphate accumulation (*Friedmanniella lacustris* has not been tested). *Friedmanniella lacustris*, *Friedmanniella capsulata*, and *Friedmanniella spumicola* are sensitive to penicillin; the latter two species were found also to be susceptible to chloramphenicol and vancomycin (Lawson et al., 2000a; Maszenan et al., 1999a). No data are available on the antibiotic sensitivity of *Friedmanniella antarctica*.

All members of the genus *Friedmanniella* exhibit the peptidoglycan type A3γ′ (A42.1, http://www.peptidoglycan-types.info) based on LL-diaminopimelic acid (LL-A_2pm), in which one glycine residue is included in the interpeptide bridge and another one is found at position 1 of the peptide subunit. The same peptidoglycan structure is found in the following members of the family *Propionibacteriaceae*: *Microlunatus* (Schumann et al., 1997), *Tessaracoccus* (Maszenan et al., 1999b), and *Propionibacterium propionicus* (Weiss et al., 1981). The predominating menaquinone is MK-9(H_4), while MK-7(H_4), MK-8(H_4), MK-7(H_2), and MK-9(H_2) may occur as minor components. $C_{15:0}$ anteiso exceeds the value of 50% in the cellular fatty acid profiles of all *Friedmanniella* strains, followed by $C_{15:0}$ iso (13.0–35.8%) and $C_{14:0}$ iso as minor component (1.8–3.9%). The polar lipids are phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, and one unidentified phospholipid. An unknown glycolipid additionally occurs in *Friedmanniella capsulata* and *Friedmanniella spumicola*. *Friedmanniella antartica* contains spermidine and spermine and corresponds in this polyamine pattern to *Microlunatus*, *Luteococcus*, and *Propioniferax* as members of the family *Propionibacteriacea* but differs from all tested species of the genera *Nocardioides* and *Aeromicrobium* of the family *Nocardioidaceae* which contains mainly cadaverine (Busse and Schumann, 1999).

Friedmanniella antarctica and *Friedmanniella lacustris* originate from Antarctica. *Friedmanniella antarctica* was isolated from a sandstone sample containing a cryptoendolithic microbial community from the Linnaeus Terrace (1600 m above ocean level), McMurdo Dry Valleys, Asgard Range of the Transarctic Mountains. *Friedmanniella lacustris* was isolated from a water sample taken at 1 m depth from the hypersaline and meromictic Ekho Lake in the ice-free area of the Vestfold Hills in East Antarctica. *Friedmanniella spumicola* was isolated from a stable surface foam of the aerobic reactor in an activated sludge plant treating mainly wastewater from an orange-juice-processing plant in Mildura, Victoria, Australia. The type strain of *Friedmanniella capsulata* was obtained from an activated sludge biomass sample from Haman Island, Queensland, Australia. Only a small number of additional strains related to *Friedmanniella spumicola* or *Friedmanniella antarctica* has been isolated from environmental habitats. *Friedmanniella* sp. Ellin 163 was isolated from pasture soil by using the liquid serial dilution culture method as described by Schoenborn et al. (2004). The 16S rRNA gene sequence of the isolate shows 99% similarity with *Friedmanniella spumicola*, but is also related to not yet cultivatable bacteria whose sequences have been submitted to EMBL. For instance, *Friedmanniella* sp. Ellin 163 shares 98–99% 16S rRNA gene sequence similarity with uncultured bacteria detected by analysis of the bacterial diversity in indoor dust (Rintala et al. not yet published; e.g., accession number AM697104) and also to sequences derived from analysis of clone libraries originating from metagenomes of endophytes and symbionts enriched from stem bark of the spurge *Trewia pudiflora*. Sequences related to *Friedmanniella spumicola* were also found in metagenomic analyses from soil as reported by Fierer et al. (2007). A *Friedmanniella spumicola*-like strain was isolated from pasture soil of perennial ryegrass (*Lolium perene*) and white clover (*Trifolium repens*) (Joseph et al., 2003), but also from 12,000 years old glacial ice, Sojana, Bolivia (Christner, 2002). Partial sequence analysis from airborne bacterial populations (Fierer

et al., 2008) led to the detection of a *Friedmanniella antarctica*-related strain (97% sequence similarity). Further 16S rRNA gene sequences from uncultured *Friedmanniella*-like bacteria were detected in soil under eucalyptus trees (Silveira et al., 2006) and bronchoalveolar lavage fluid from children with cystic fibrosis (Harris et al., 2007) showing similarity values of 98% to *Friedmanniella capsulata* and 97% to *Friedmanniella antarctica*.

Isolation and maintenance procedures

Friedmanniella antartica was isolated by sprinkling of loosened sandstone material onto PYGV agar (pH 6.9). Colonies developed around sand grains after incubation for 5 months at 9°C in dim light were picked and streaked onto the same medium. Resulting single colonies were subcultured after

[g]Reactions variable in different test systems.

5 months on PYGV agar slants at 4–6°C. Serial transfers at 2-week intervals on R-agar at 22°C under diffuse daylight kept the type strain viable. Strain AA-1042[T] could be recultivated successfully from lyophilized conserves stored at 4°C for 27 months (Schumann et al., 1997). *Friedmanniella antarctica* DSM 11053[T] and *Friedmanniella capsulata* DSM 12936[T] could also be recovered successfully from freeze-dried cultures after a 10 year period of storage. Viability testing revealed 10^3–10^5 c.f.u./ml depending on the growth behavior of the strain (strength of aggregating packets and cluster formation).

The type strains of *Friedmanniella spumicola* and *Friedmanniella capsulata* were isolated from a foam sample and activated sludge biomass, respectively, by micromanipulation (Skerman, 1968). Colonies of both strains developed on standard methods agar (SMA, Difco) supplemented with 1% sterile horse serum at 25°C after 7–10 d. Subsequent purification was done on R2A agar. Short-term storage is possible in R2A or trypticase soy yeast extract medium containing 20% glycerol at −80°C. At the DSMZ, cultures are freeze-dried for long-term conservation according to described procedures which have been summarized in the Cabri guidelines (www.Cabri.org). In addition, preservation by freezing and low temperature storage in glass capillary tubes can be applied. *Friedmanniella lacustris* was isolated from a 20 ml water sample after enrichment by inoculation into 100 ml autoclaved PYGV medium (pH 8.0) prepared with filtered Ekho Lake water for 12 d at 15°C. Single colonies of strain EL17A[T] were obtained after streaking the enrichment culture onto PYGV agar. Cultures of the strain were freeze-dried and stored at 8°C in the dark.

Procedures for testing special characteristics

Because the peptidoglycan type A3γ′, variation A42.1, is a significant feature of members of the genera *Friedmanniella*, *Microlunatus*, *Tessaracoccus*, and of *Propionibacterium propionicus*, refer to the chapter on the genus *Terracoccus* (this volume) where the elucidation of the peptidoglycan structure is described. The structural variation A42.1 of the peptidoglycan based on LL-A_2pm can be concluded from the occurrence of the peptide Gly→D-Glu instead of the dipeptide L-Ala→D-Glu which is commonly found in A-type peptidoglycans (Schleifer and Kandler, 1972). The structure is confirmed by the molar ratio of the amino acids of ca. 1 LL-A_2pm:1 Glu:2 Gly:1 Ala, determined by gas chromatography as described by MacKenzie (1987).

Differentiation of the genus *Friedmanniella* from closely related genera

The genera with the highest phylogenetic relationship to the genus *Friedmanniella* are *Microlunatus* (Nakamura et al., 1995), *Micropruina* (Shintani et al., 2000), *Propionicicella* (Bae et al., 2006c), and *Propionicimonas* (Akasaka et al., 2003b). The genera *Micropruina*, *Propionicicella*, and *Propionicimonas* differ from the genus *Friedmanniella* in displaying the diagnostic diamino acid *meso*-A_2pm (Table 208). The latter two species can also be differentiated by their morphology. The unsaturated menaquinone MK-9 was reported for the genus *Propionicicella* (Bae et al., 2006c) which is unique within the families *Propionibacteriaceae* and *Nocardioidaceae*. The menaquinone profile of *Propionicimonas* differs from that of the genus *Friedmanniella* by the additional occurrence of MK-10(H_4) (Akasaka et al., 2003b). The genus *Microlunatus* shares not only the highest 16S rRNA gene sequence similarity with *Friedmanniella antarctica* but also peptidoglycan structure, major cellular fatty acids, menaquinone, and polar lipids (Table 208). As distinguishing chemotaxonomic characteristics are lacking, the differentiation of the genera *Friedmanniella* and *Microlunatus* is based on the lower tendency to aggregate and to form capsular polymers, better growth in submerged cultures, lack of orange pigments, and metabolism of a broader range of organic compounds of strains of the lat-

TABLE 208. Characteristics differentiating the genus *Friedmanniella* from the phylogenetically related genera *Microlunatus*, *Micropruina*, *Propionicicella*, and *Propionicimonas*[a]

ter genus (Schumann et al., 1997). The differentiation of both genera by the oxidase test (Maszenan et al., 1999a; Schumann et al., 1997) lost its importance as Lawson et al. (2000a) reports a weak oxidase reaction also for *Friedmanniella lacustris* and as the second *Microlunatus* species, *Microlunatus ginsengisoli* (Cui et al., 2007), differs from the type species of *Microlunatus* in its negative oxidase reaction. Members of the genus *Mirolunatus* differ from *Friedmanniella* species (except for *Friedmanniella lacustris*) in their capability to reduce nitrate. Several physiological and biochemical traits contribute to the differentiation of *Friedmanniella* and *Microlunatus* species (see Table 207).

Taxonomic comments

Stackebrandt and Schaal (2006b) considered the genus *Friedmanniella* as well as the genus *Micropruina* members of the family *Propionibacteriaceae* Delwiche (1957), emend. Rainey, Ward-Rainey and Stackebrandt (1997), while both genera were listed as members of the family *Nocardioidaceae* Nesterenko et al., (1985), emend. Rainey, Ward-Rainey and Stackebrandt (1997) in the Taxonomic Outline of the *Bacteria* and *Archaea* (Garrity et al., 2007). Because members of the genus *Friedmanniella* represent a phylogenetic subcluster within the clade of the family *Propionibacteriaceae* as shown in Figure 239, and because the peptidoglycan type A3γ′ in combination with the major menaquinone MK-9(H_4) and the polyamines spermidine and spermine can only be found in members of the family *Propionibacteriaceae*, the authors of this chapter take the view of Stackebrandt and Schaal (2006b) that the genus *Friedmanniella* shares the membership in the family *Propionibacteriaceae* with the genera *Propionibacterium*, *Luteococcus*, *Microlunatus*, *Micropruina*, *Propioniferax*, *Propionimicrobium*, and *Tessaracoccus* but also with *Propionicimonas* (Akasaka et al., 2003b), *Propionicicella* (Bae et al., 2006c), *Aestuariimicrobium* (Jung et al., 2007), *Granulicoccus* (Maszenan et al., 2007), and *Brooklawnia* (Bae et al., 2006b). The species *Jiangella gansuensis* YIM 002[T] (Song et al., 2005) was excluded from the phylogenetic analysis because all sequences available at present from EMBL and NCBI database are assigned to the family *Pseudonocardiaceae.* The EzTazon (Chun et al., 2007) also does not place the strain into the family *Nocardioidaceae* as stated by Song et al. (2005).

The species of the genus *Friedmanniella* are clearly differentiated from one another by their metabolic properties (Table 207). Both *Microlunatus* species were included in Table 207, as biochemical and physiological properties are useful for the differentiation of *Friedmanniella* and *Microlunatus* species. *Friedmanniella lacustris* and *Friedmanniella capsulata* are the metabolically most versatile organisms of the genus while *Friedmanniella antarctica* shows the lowest amount of positive reactions. *Friedmanniella lacustris* differs from the other members of the genus by lacking H_2S production, tolerance of up to 6% NaCl, growth below 9°C, and its ability to hydrolyze gelatin and reduce nitrate. The growth of *Friedmanniella capsulata* and *Friedmanniella spumicola* is inhibited by addition of NaCl to the media.

Acknowledgements

This chapter is dedicated to Dr. Helmut Prauser on the occasion of his 80th birthday in honor of his contribution to pioneering work on the taxonomy of actinomycetes and of the genera *Nocardioides* and *Friedmanniella* in particular.

List of species of the genus *Friedmanniella*

1. **Friedmanniella antarctica** Schumann, Prauser, Rainey, Stackebrandt and Hirsch 1997, 282[VP]

an.tarc′ti.ca. L. fem. adj. *antarctica* southern, isolated from Antarctica.

The spherical cells are 0.5–2.2 mm in diameter. The cells are arranged in more or less regular packets which adhere to one another to form clusters. Growth in submerged standing and shaking cultures is slow and poor. Colonies on R agar are up to 2 mm in diameter and raised and have irregular edges and shapes. The colony surface is crumbly and dull to smooth and shiny depending on the growth medium. The orange color of colonies may become more intense when the organism is cultured in diffuse daylight. The optimum growth temperature is 22°C. The temperature range for growth is approximately 9–25°C; no growth occurs at 6°C and 28°C. The optimal pH range for growth is 6.0–7.2. Catalase-positive. Oxidase-negative. Urease-positive. Does not reduce nitrate to nitrite. Acid is produced from D-ribose, is produced weakly from L-arabinose, and is produced very weakly from D-xylose. No acid is produced from L-rhamnose, D-glucose, D-fructose, D-mannose, D-galactose, maltose, lactose, sucrose, D-cellobiose, trehalose, D-raffinose, glycerol, D-mannitol, and *myo*-inositol. Starch and esculin are hydrolyzed, and Tween 80 and DNA are only weakly hydrolyzed. Casein and gelatin are not hydrolyzed. Sodium formate is utilized as a carbon source. Sodium acetate, sodium aconitate, sodium benzoate, sodium citrate, disodium succinate, and potassium hydrogentartrate are not utilized. Hypoxanthine, xanthine, adenine, DL-tyrosine, and sodium hippurate are not decomposed. H_2S is produced.

DNA G+C content (mol%): 73 (HPLC).

Type strain: AA-1042, DSM 11053, JCM 11651, NBRC 16127.

Sequence accession no. (16S rRNA gene): Z78206.

2. **Friedmanniella capsulata** Maszenan, Seviour, Patel, Schumann, Burghardt, Webb, Soddell and Rees 1999a, 1678[VP]

cap.su.la′ta. L. n. *capsula* a small box or chest; L. fem. suff. *-ata* suffix denoting provided with; N.L. fem. adj. *capsulata* with a chest, capsuled.

This species is characterized by a bright orange color when grown in both solid and liquid media. Cell diameter is 0.6–1.2 µm. Can store polyphosphate aerobically. The optimum growth temperature is 20–25°C. The pH range for growth is 5.5–7.5, with an optimal growth pH of 6.5–7.0. Utilizes L-rhamnose, maltose, sucrose, β-cyclodextrin, L-fucose, 2-aminoethanol, 2,3-butanediol, glucose 6-phosphate, maltotriose, sedoheptulosan, stachyose, D-tagatose, lactamide, 2′-deoxyadenosine, α-ketoglutaric acid, propionic acid, succinamic acid, 3-methylglucose, bromosuccinic acid, glucuronamide, D-alanine, L-alanyl glycine, L-asparagine, L-aspartic acid, glycyl-L-aspartic acid, L-histidine, hydroxy-L-proline, L-threonine, DL-carnitine, γ-aminobutyric acid, urocanic acid, inosine, D-melezitose, malate, and trypsin. The following substrates are not utilized: *i*-erythritol, D-saccharic acid, formic acid, adonitol, D-galactose, D-psicose, turanose, methyl-pyruvate, α-ketobutyric acid, alaninamide, and thymidine. Cellular fatty acid profile is characterized by the presence of $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{17:0}$ anteiso. Contains the menaquinones MK-9(H_4) and MK-9(H_2) and characterized by the presence of MK-7(H_4). Mycolic acids are absent.

Type strain: Ben 108, ACM 5120, CCUG 43143, DSM 12936, JCM 13522.

Sequence accession no. (16S rRNA gene): AF084529.

3. **Friedmanniella lacustris** Lawson, Collins, Schumann, Tindall, Hirsch and Labrenz 2000b, 1953[VP] (Effective publication: Lawson, Collins, Schumann, Tindall, Hirsch and Labrenz 2000a, 226.)

la.cus′tris. N.L. fem. adj. *lacustris* (from L. n. *lacus*, a lake) belonging to the lake.

Cocci with some extracellular polymer, in older cultures also short rods. Cells nonmotile, 0.9–1.3 µm, nonsporeforming, aggregating in short chains, tetrads, or even packets. Grow well on medium PYGV + ASW containing vitamins. Agar colonies flat, watery, and slimy, with a brownish to pink color; older colonies more orange. Aerobic heterotrophs; carbon sources utilized for growth are acetate (weakly), pyruvate, α-D-glucose, glutamate, and citrate, but does not grow on succinate, malate, butyrate, or methanol. A large number of sugar compounds and several organic acids offered by the Biolog GP test system are metabolized. Polymers hydrolyzed: gelatin, starch, and DNA (weakly); does not hydrolyze alginate, casein, or Tween 80. Requires biotin, thiamine, and nicotinic acid for growth. Nitrate is weakly reduced aerobically. NH_3 is formed from peptone; produces acids from glucose. Voges–Proskauer, indole formation, and H_2S production-negative. Temperature optimum is 26°C; the range for growth is 3–3.5°C. The pH tolerance range for growth is 5.5–9.5, with an optimum at pH 7.5. Tolerates up to 6% (w/v) of NaCl with an optimum at 4%. Sensitive to chloramphenicol, penicillin G, and vancomycin. Peptidoglycan type is A3γ′ based on LL-diaminopimelic acid, a single glycine residue as interpeptide bridge, and a glycine residue at position 1 of the peptide subunit. Cell-wall sugars: glucose, mannose, ribose, rhamnose, and galactose. The major respiratory lipoquinone is MK-9(H_4) (83%), with MK-8(H_4) (4%) as minor component. Major fatty acids: $C_{15:0}$ anteiso and $C_{15:0}$ iso. Polar lipids include phosphatidylinositol, phosphatidylglycerol, diphosphatidylglycerol, and an unidentified phospholipid. Mycolic acids absent.

DNA G+C content (mol%): 73 (HPLC).

Type strain: EL-17A, ATCC BAA-165, CIP 106992, DSM 11465, JCM 11951, NCFB 3066.

Sequence accession no. (16S rRNA gene): AJ132943.

4. **Friedmanniella spumicola** Maszenan, Seviour, Patel, Schumann, Burghardt, Webb, Soddell and Rees 1999a, 1678[VP]

spu.mi′co.la. L. fem. n. *spuma* foam; L. suffix *-cola* inhabitant; N.L. masc./fem. n. *spumicola* inhabitant of foam.

Cells adhere to one another and form aggregates of four and eight. The cell diameter is 0.5–1.4 µm. Growth in liquid and solid media is slow and poor requiring up to 2 weeks. Colony color when grown on solid and liquid media is dark yellow to pale orange. The temperature range for growth is 15–37°C with an optimum temperature of 25°C. The pH range for growth is 5.5–8.0, with an optimum pH of 7.0–7.5. Cells store PolyP granules aerobically. Can utilize the following substrates: i-erythritol, D-saccharic acid, formic acid, D-galactose, turanose, methylpyruvate, α-ketobutyric acid, alaninamide, and thymidine. The following substrates were not utilized: L-rhamnose, maltose, sucrose, β-cyclodextrin, L-fucose, 2-aminoethanol, 2,3-butanediol, glucose 6-phosphate, maltotriose, sedoheptulosan, stachyose, D-tagatose, lactamide, 2′-deoxyadenosine, α-ketoglutaric acid, propionic acid, succinamic acid, glucuronamide, D-alanine, L-alanyl-glycine, L-asparagine, L-aspartic acid, glycyl-L-aspartic acid, L-histidine, hydroxy-L-proline, L-threonine, DL-carnitine, γ-aminobutyric acid, uroconic acid, inosine, D-melezitose, malate, 3-methylglucose, bromosuccinic acid, and trypsin. Characterized by the presence of $C_{18:1}$ and $C_{15:0}$ iso. Unbranched fatty acids with 14, 15, and 16 carbons were found in trace amounts. Its major menaquinones are MK-9(H_4) and MK-7(H_2), with MK-9(H_2), MK-8(H_2), and MK-8(H_4) present in trace amounts. Mycolic acids are absent.

Genus V. **Granulicoccus** Maszenan, Jiang, Tay, Schumann, Kroppenstedt and Tay 2007, 733[VP]

THE EDITORIAL BOARD

Gra.nu.li.coc′cus. L. neut. n. *granulum* a small grain; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Granulicoccus* a coccus from (sludge) granules, here referring to the isolation source.

Non-spore-forming coccus (0.3–1.4 µm diameter). **Gram-stain-positive**. Nonmotile. **Facultative anaerobe**. Temperature range for growth 15–37°C, pH range 5–8.5. Cell wall contains type A3γ peptidoglycan (LL-A_2pm←Gly with alanine at position 1 of the peptide subunit). MK-9(H_4) is the major menaquinone, MK-8(H_4) is present as well in a 42:1 compositional ratio. Polar lipid profile comprises diphosphatidylglycerol and phosphatidylglycerol.

DNA G+C content (mol%): 69.

Type species: **Granuliococcus phenolivorans** Maszenan, Jiang, Tay, Schumann, Kroppenstedt and Tay 2007, 733[VP].

Further descriptive information

Major fatty acids are 13-methyltetradecanoic acid ($C_{15:0}$ iso, 50.5%) and 1,1-dimethoxy-iso-pentadecane ($C_{15:0}$ iso DMA, 37.4%). Stains contain polyphosphate granules but not poly-β-hydroxyalkanoates. Produces capsular material and can autoaggregate.

Phylogenetic analysis of the 16S rRNA gene affiliates the genus with the family *Propionibacteriaceae*. The closest phylogenetic neighbors are *Luteococcus peritonei* (93.9% sequence similarity) (Collins et al., 2000), *Microlunatus panaciterrae* (93.6%) (An et al., 2008), and *Propioniferax innocua* (93.6%) (Pitcher and Collins, 1991; Yokota et al., 1994).

Enrichment and isolation procedures

Strain PG-02[T] was isolated from phenol-degrading aerobic granules cultivated in a laboratory-scale sequencing batch reactor fed with synthetic wastewater containing phenol as the sole carbon source (Jiang et al., 2004). Activated sludge was the initial seed for the reactor. Granules (2.5 g) were added to 15 ml MP medium, and serial diluents of the supernatant were spread onto agar plates containing MP medium with 1.2% Bacto agar (Difco). Plates were incubated for 28 d at 25°C (2007). Colony morphology is visible after 10 d of incubation on MP agar plates.

Maintenance procedures

Strain PG-02[T] can be grown on synthetic wastewater medium with phenol as the sole carbon source with the following composition (per liter): phenol, 0.5 g; NH_4Cl, 0.20; $MgSO_4·7H_2O$, 0.13 g; K_2HPO_4, 1.65 g; KH_2PO_4, 1.35 g; and 1 ml of micronutrient solution. Stock cultures are maintained as a 20% glycerol suspension at −80°C.

Differentiation of the genus *Granuliococcus* from closely related genera

Presence of $C_{15:0}$ iso DMA differentiates *Granulicoccus* from the related genera *Luteococcus*, *Friedmanniella*, *Tessaracoccus*, *Propioniferax*, *Micropruina* and *Microlunatus*. *Granulicoccus* differs from *Microlunatus* in the possession of MK-8(H_4) and lack of phosphatidylinositol. The pleomorphic rod morphology and the polar lipid phosphatidylethanolamine of *Propioniferax* distinguish it from *Granulicoccus*.

List of species of the genus *Granuliococcus*

1. **Granulicoccus phenolivorans** Maszenan, Jiang, Tay, Schumann, Kroppenstedt and Tay 2007, 733^{VP}

phe.no.li.vo′rans. N.L. neut. n. *phenolum* phenol; L. part. adj. *vorans* devouring, consuming; N.L. part. adj. *phenolivorans* consuming phenol.

Growth occurs at mesophilic temperature and pH 5–8.5, with optima at 30°C and pH 7. Arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase and tryptophan deaminase tests are negative. H_2S and indole are not produced. Voges–Proskauer-negative and does not produce acetoin or reduce nitrate to nitrite. Catalase-positive and oxidase-negative. Utilizes phenol, Tweens 40 and 80, L-arabinose, α-D-glucose, α-D-lactose, lactulose, maltose, maltotriose, D-mannose, D-melezitose, D-melibiose, methyl α-D-galactoside, methyl β-D-galactoside, 3-methyl glucose, methyl α-D-glucoside, methyl β-D-glucoside, psicose, D-raffinose, L-rhamnose, D-ribose, salicin, sedoheptulosan, stachyose, sucrose, D-tagatose, D-trehalose, turanose, D-xylose, *myo*-inositol, D-mannitol, D-sorbitol, xylitol, 2,3-butanediol, glycerol, DL-α-glycerol phosphate, glucose 1-phosphate, glucose 6-phosphate, adenosine, AMP, TMP, UMP and fructose 6-phosphate (Biolog GN and GP systems and API 20E). Acids and their derivatives utilized include methyl pyruvate, monomethyl succinate, acetic acid, citric acid, D-galactonic acid lactone, D-gluconic acid, D-glucuronic acid, α-, β- and γ-hydroxybutyric acids, *p*-hydroxyphenylacetic acid, itaconic acid, α-ketobutyric acid, α-ketoglutaric acid, α-ketovaleric acid, lactamide, D-lactic acid methyl ester, L- and DL-lactic acid, D- and L-malic acid, propionic acid, pyruvic acid, quinic acid, D-saccharic acid, sebacic acid, succinic acid, bromosuccinic acid, succinamic acid, *N*-acetylglutamic acid, L-glutamic acid, glycyl L-glutamic acid and L-pyroglutamic acid. Amino acid compounds utilized glucuronamide, alaninamide, D-alanine, L-alanine, L-alanyl glycine, L-asparagine, L-phenylalanine, L-proline, L-serine, inosine, uridine, thymidine and putrescine. Gentiobiose is weakly utilized. Growth is not affected by α-cyclodextrin, β-cyclodextrin, dextrin, glycogen, inulin, mannan, amygdalin, adonitol, D-arabitol, arbutin, cellobiose, i-erythritol, D-fructose, L-fucose, D-galactose, 2-aminoethanol, *N*-acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, *N*-acetylmannosamine, phenyl ethylamine, deoxyadenosine, L-histidine, hydroxy-L-proline, L-leucine, L-ornithine, D-serine, L-threonine, DL-carnitine, D-galacturonic acid, formic acid, D-glucosaminic acid, malonic acid, L-aspartic acid, γ-aminobutyric acid and urocanic acid. Both the API ZYM and API 20E detect alkaline phosphatase, esterase, lipase, leucine arylamidase, valine arylamidase, naphthol-AS-BI-phosphohydrolase, α-galactosidase, β-galactosidase, β-glucuronidase, α-glucosidase and β-glucosidase. API 20E also detects β-galactosidase, urease and gelatinase. API ZYM did not detect acid phosphatase, esterase lipase, cystine arylamidase, trypsin, chymotrypsin, *N*-acetyl-β-glucosaminidase, α-mannosidase and α-fucosidase.

For all other characteristics, refer to the genus description.

DNA G+C content (mol%): 69 (HPLC).

Type strain: PG-02^T ATCC BAA-1292, DSM 17626.

Sequence accession no. (16S rRNA gene): AY566575.

Genus VI. **Luteococcus** Tamura, Takeuchi and Yokota 1994, 355^{VP} emend. Collins, Lawson, Nikolaitchouk and Falsen 2000, 181

TOMOHIKO TAMURA

Lu.te.o.coc′cus. L. adj. *luteus* yellow; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Luteococcus* yellow coccus.

Gram-stain-positive coccus or pleomorphic rod. Spherical cells are 0.7–1.0 μm in diameter and occur **singly, in pairs, or in tetrads**. Nonsporeforming. Colonies are circular and smooth and may be cream colored to yellow. **Facultatively anaerobic**. Catalase- and oxidase-positive. Urease-negative. The cells may or may not reduce nitrate to nitrite. Starch is hydrolyzed. Tween 20, 40, 60, and 80 are not hydrolyzed. Acid is produced from glucose and some other sugars. Propionic acid is the major product formed from glucose. Optimum growth temperature is 26–28°C.

Cell-wall peptidoglycan contains **LL-diaminopimelic acid**, alanine, glycine, and glutamate (approximately 1:2:1:1). The major menaquinone is MK-9(H_4). Mycolic acid is not present. The major cellular fatty acid is $C_{16:1}$, and among the minor components a small amount of $C_{18:0}$ iso 2OH is also present. Arabinose is present as a diagnostic sugar in the cell wall. The polar lipids phosphatidylinositol, diphosphatidyiglycerol, and phosphatidyiglycerol, are present.

DNA G+C content (mol%): 64–67.

Type species: **Luteococcus japonicus** Tamura, Takeuchi and Yokota 1994, 355^{VP}.

Further descriptive information

The description of the genus *Luteococcus* has been emended by Collins et al. (2000) to include pleomorphic rods as well as cocci. The type species grows well at temperatures of 25–30°C on oatmeal agar, inorganic salts-starch agar, and peptone-yeast extract-iron agar. For chemotaxonomic studies, these strains were grown in shake cultures (nutrient broth; Difco) at 28°C, and cells were harvested in the stationary phase, washed twice with water, and then, if necessary, freeze-dried.

Cellular fatty acids of the genus *Luteococcus* comprise predominantly $C_{15:1}$, $C_{17:1}$, and $C_{18:1}$ in addition to $C_{16:1}$. The composition differs among species. *Luteococcus peritonei* and *Luteococcus sanguinis* contains predominantly $C_{17:1}$ and followed by $C_{16:1}$ and $C_{15:1}$.

Other properties of the species of *Luteococcus* are presented in Table 209.

Enrichment and isolation procedures

The two strains of *Luteococcus japonicus* were isolated from soil on Tokara Island, Japan, and from spring water for brewing

named "miyamizu" in Hyogo prefecture, Japan, respectively (Oda, 1935). *Luteococcus peritonei* was isolated from human peritoneum during a fetal autopsy. *Luteococcus sanguinis* was isolated from a blood sample (one out of four bottles) of a 32-year-old man. Although the latter two species were isolated from human samples, the pathogenicity is not known.

Maintenance procedures

The strains of the genus *Luteococcus* are maintained by freezing in water containing 10–30% glycerol at −70°C. Lyophilization of suspensions in 10% skim milk + 1% monosodium glutamate and l-drying in 0.01 M potassium phosphate buffer (pH 7.0) containing 3% monosodium glutamate are also recommended for long-term preservation.

Differentiation of the genus *Luteococcus* from other genera

Luteococcus species show the same chemotaxonomic characteristics as most other genera of the family *Propionibacteriaceae* in possessing a cell-wall peptidoglycan containing LL-diaminopimelic acid (LL-A_2pm) and menaquinone MK-9(H_4). However, the cellular fatty acid composition containing predominantly straight monounsaturated acids (approximately 90% of total acids) is unusual and characteristic for the genus *Luteococcus* (Collins et al., 2000, 2003; Tamura et al., 1994). In contrast, the other members of the family *Propionibacteriaceae* possess mostly iso- and anteiso-branched fatty acids.

Taxonomic comments

Based on 16S rRNA gene sequence analysis, the species of the genus *Luteococcus* form an independent clade in the family *Propionibacteriaceae* of the order *Propionibacteriales*. Within the genus, phylogenetic distances based on 16S rRNA gene sequences between *Luteococcus peritonei* and the other two species are both 94%, indicating the distinctness of this species. In contrast, the sequence difference between *Luteococcus japonicus* and *Luteococcus sanguinis* is 96.9%, indicative of a closer relationship (Collins et al., 2003). However, species status was confirmed by the low DNA relatedness of 49% between these species (Collins et al., 2003). These relationships are confirmed by a comparison of the other phenotypic properties of these species, where *Luteococcus japonicus* and *Luteococcus sanguinis* share similarities in morphologies and carbon sources not seen in *Luteococcus peritonei* (Table 209).

Differentiation of species of the genus *Lutoecoccus*

Luteococcus peritonei can be distinguished from *Luteococcus japonicus* and *Luteococcus sanguinis* by its pleomorphic rod-shaped morphology. Nitrate is reduced to nitrite by *Luteococcus peritonei* and *Luteococcus sanguinis* but not by *Luteococcus japonicus*.

List of species of the genus *Luteococcus*

1. **Luteococcus japonicus** Tamura, Takeuchi and Yokota 1994, 355[VP]

ja.po′ni.cus. N.L. masc. adj. *japonicus* of or pertaining to Japan, where the organisms were isolated.

Cells are spherical and 0.7–1.0 µm in diameter and occur singly, in pairs, or in tetrads. Nonsporeforming. Gram-stain-positive. Facultatively anaerobic. Colonies are circular and smooth and may be cream colored to yellow. Catalase- and oxidase-positive. Urease-negative. Nitrate is not reduced to nitrite. Oxidation-fermentation is fermentative. Acid is produced from D-glucose, D-ribose, D-galactose, D-mannose, D-fructose, sucrose, maltose, trehalose, raffinose, glycerol, mannitol, inositol, and L-arabinose but not from D-xylose, D-arabinose, or L-rhamnose. Propionic acid is produced from glucose. Starch is hydrolyzed. Gelatin is weakly or not hydrolyzed. Optimum growth temperature is 26–28°C.

Type strain: ATCC 51526, CCUG 38731, CIP 104067, DSM 10546, JCM 9415, NBRC 12422, VKM Ac-1951.

Sequence accession no. (16S rRNA gene): D21245, D85487, Z78208.

2. **Luteococcus peritonei** Collins, Lawson, Nikolaitchouk and Falsen 2000, 181[VP]

pe.ri.to.ne′i. L. n. *peritoneum* peritoneum; L. gen. neut. n. *peritonei* of the peritoneum.

Cells consist of pleomorphic rods that are Gram-stain-positive. Pigment is not produced. Facultatively anaerobic and catalase-positive. Acid is produced from glucose, lactose, sucrose, mannitol, and methyl β-D-glucopyranoside. Acid may or may not be produced from maltose. Acid is not produced from L-arabinose, D-arabitol, cyclodextrin, glycogen, melibiose, melezitose, pullulan, ribose, raffinose, sorbitol, trehalose, tagatose, or D-xylose. Esculin is hydrolyzed but gelatin and hippurate are not. α-Galactosidase, β-galactosidase, β-galacturonidase, α-glucosidase, β-glucosidase, β-glucuronidase, leucine arylamidase, and pyrazinamidase are produced. Arginine dihydrolase, lipase C14, chymotrypsin, α-fucosidase, glycyl-tryptophan arylamidase, *N*-acetylglucosaminidase, α-mannosidase, β-mannosidase, pyroglutamic acid arylamidase, trypsin, valine arylamidase, and urease are not produced. Activity for alkaline phosphatase and acid phosphatase may or may not be detected. Voges–Proskauer reaction is negative. Nitrate is reduced to nitrite.

Source: human peritoneum.

DNA G+C content (mol%): 65 (method of determination not reported).

Type strain: ATCC BAA-60 = CCUG 38120 = CIP 106441 = JCM 11685.

Sequence accession no. (16S rRNA gene): AJ132334.

3. **Luteococcus sanguinis** Collins, Hutson, Nikolaitchouk, Nyberg and Falsen 2003, 1891[VP]

san′gui.nis. L. gen. n. *sanguinis* of blood.

Nonmotile coccus; Gram-stain-positive. Facultatively anaerobic and catalase-positive.

Acid is produced from glucose, glycogen, mannitol, maltose, lactose, and sucrose, but not from ribose or D-xylose. Esculin and gelatin are hydrolyzed. When tested by using commercial API Coryne and API ZYM systems, acid phosphatase (weak reaction), alkaline phosphatase, chymotrypsin, ester lipase C8 (weak), cystine arylamidase (weak), α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, leucine arylamidase, phosphoamidase (weak), pyrrolidonyl arylamidase, pyrazinamidase, valine arylamidase (weak), and trypsin are detected. Esterase C4, lipase C14, α-fucosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, pyroglutamic acid arylamidase, and urease are not detected. Voges–Proskauer reaction is negative. Nitrate is reduced to nitrite.

Source: human blood.

DNA G+C content (mol%): 64 (method of determination not reported).

Type strain: CCUG 33897 = CIP 107216 = JCM 12371.

Sequence accession no. (16S rRNA gene): AJ416758.

Genus VII. **Microlunatus** Nakamura, Hiraishi, Yoshimi, Kawaharasaki, Masuda and Kamagata 1995, 21[VP]

Satoshi Hanada and Kazunori Nakamura

Mi.cro.lu.na′tus. Gr. adj. *mikros* small; L. masc. adj. *lunatus* half moon-shaped; N.L. masc. n. *Microlunatus* small moon-like microorganism.

Coccoid or spherical cells, 0.3–2.0 µm in diameter. Occurs singly and in pairs. Occasionally forms clusters. Some species show rod-shaped morphology. **Gram-stain-positive**. Nonmotile. Nonsporeforming. Catalase-positive. **Mesophilic**. Good growth occurs at 20–30°C. **Aerobic and chemo-organotrophic**. The following sugars and sugar alcohols can support good growth: glucose, arabinose, mannose, maltose, melibiose, rhamnose, and sorbitol. Some species reduce nitrate under anaerobic conditions and accumulate phosphate inside cells. The major quinone is MK-9(H_4). The cell-wall peptidoglycan contains LL-diaminopimeric acid. The major fatty acids are $C_{15:0}$ anteiso, $C_{15:0}$ iso, and $C_{16:0}$ iso. Isolated from activated sludge in wastewater treatment system, soil, spawn of a mushroom, and an indoor wall.

DNA G+C content (mol%): 65.1–70.9.

Type species: **Microlunatus phosphovorus** Nakamura, Hiraishi, Yoshimi, Kawaharasaki, Masuda and Kamagata 1995, 21[VP].

Further descriptive information

Microlunatus phosphovorus, the type species of the genus, was isolated from activated sludge in the wastewater treatment process (Nakamura et al., 1995). The process, consisting of alternating anaerobic and aerobic conditions, was designed to exhibit high phosphate removal activity. Because *Microlunatus phosphovorus* can accumulate a large amount of phosphate inside cells as a polyphosphate, it is considered to significantly contribute to phosphate removal from wastewater. The uptake and accumulation of phosphate are observed under aerobic conditions. Conversely, the accumulated polyphosphate is degraded and released outside under anaerobic conditions. Such phosphate uptake under aerobic conditions is also found in *Microlunatus aurantiacus*, but the amount of accumulation is obviously smaller than that of *Microlunatus phosphovorus* (Wang et al., 2008).

The cells of *Microlunatus phosphovorus* are 0.8–2.0 µm in diameter and occurred singly or in pairs (Figure 240). Small irregular clusters of cells are occasionally formed. A cell-wall structure (segmentation) is frequently observed in the middle of the spherical cells (Figure 241).

The species of the genus *Microlunatus* are mesophilic and neutrophilic and show good growth at 25–30°C and around pH 7.0. Nitrate reduction under anaerobic condition was included in the description of the genus based on the characteristic of *Microlunatus phosphovorus*. However, *Microlunatus ginsengsoli* and *Microlunatus panaciterrae* are negative for nitrate reduction. Although some species can reduce nitrate to nitrite under anaerobic conditions, the genus *Microlunatus* is basically a chemo-organotroph which grows by oxygen respiration using sugars and sugar alcohols as substrates.

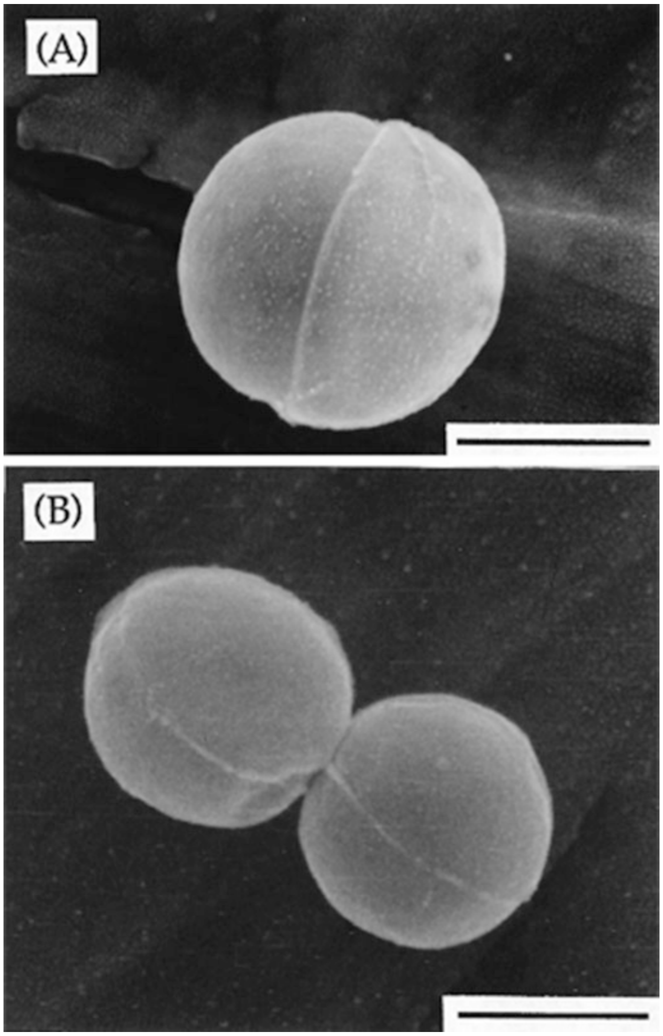

FIGURE 240. Scanning electron micrographs the type strain of *Microlunatus phosphovorus*. (A) Single cell. (B) Cells in pair. Bars = 1 μm. (Reproduced with permission from Nakamura et al., 1995. Int. J. Syst. Bacteriol. *45*: 17–22.)

In addition to *Microlunatus phosphovorus* as the type species, the genus *Microlunatus* contains five species. *Microlunatus ginsengisoli*, *Microlunatus aurantiacus*, and *Microlunatus panaciterrae* were all isolated from soil (An et al., 2008; Cui et al., 2007; Wang et al., 2008). While *Microlunatus phosphovorus* is slow growing with a doubling time of 13 h, two species of these isolates from soil, i.e., *Microlunatus ginsengisoli* and *Microlunatus panaciterrae*, can grow quickly on R2A medium. *Microlunatus soli* and *Microlunatus parietis* were isolated from the spawn of the mushroom *Agaricus brasiliensis* and an indoor wall, respectively. They are both oxidase-positive species like *Microlunatus panaciterrae*. *Microlunatus soli* contains unsaturated fatty acids, e.g., $C_{18:1}$ ω7*c*, that are rarely found in any other *Microlunatus* species.

The peptidoglycan structure of the genus *Microlunatus* was determined for *Microlunatus phosphovorus* (Schumann et al., 1997) and *Microlunatus soli* (Kämpfer et al., 2010b) and reveals that the interpeptide bridge is a single glycine and that position 1 of the peptide subunit is substituted by glycine. The structure is designated A3γ′ according to the classification of Schleifer and Kandler (1972).

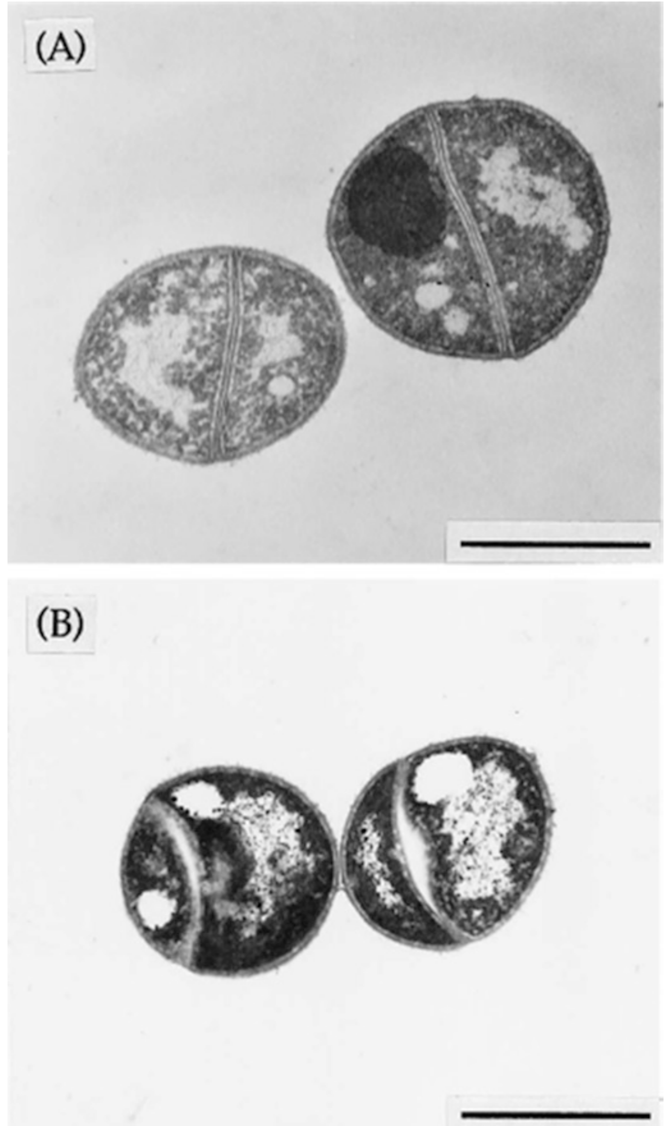

FIGURE 241. Transmission electron micrographs of thin sections of *Microlunatus phosphovorus* showing cell-wall structure in the middle of spherical cells and accumulation of polyphoisphate. (A) Cells harvested at the exponential phase. (B) Cells harvested at the stationary phase showing intracellular storage of polyphosphate (clear areas). Bars = 1 μm. (Reproduced with permission from Nakamura et al., 1995. Int. J. Syst. Bacteriol. *45*: 17–22.)

Although these six species of the genus *Microlunatus* have almost similar phenotypic characteristics as mentioned in the genus description above, they can be differentiated by comparing oxidase activity, nitrate reduction under anaerobic conditions, phosphate accumulation, and/or nutritional profiles (Table 210).

Enrichment and isolation procedures

For isolation of *Microlunatus phosphovorus*, a slow-growing bacterium inhabiting activated sludge, a relatively oligotrophic medium is used. Such an oligotrophic medium inhibits fast-growing bacteria from predominating. The isolation medium contains the following ingredients (per liter): 0.5 g of glucose, 0.5 g of peptone, 0.5 g of monosodium glutamate, 0.5 g of yeast

extract, 0.44 g of KH_2PO_4, 0.1 g of $(NH_4)_2SO_4$, and 0.1 g of $MgSO_4 \cdot 7H_2O$ (pH adjusted to 7.0 with NaOH). Activated sludge (obtained from the wastewater treatment process with alternating anaerobic and aerobic conditions that exhibits high phosphate removal activity) is gently dispersed with an ultrasonicator and streaked on the isolation medium solidified with 1.5% agar. Circular, smooth, convex, and buff colonies of *Microlunatus phosphovorus* emerge on an agar plate after a few weeks of incubation at 25°C. The same liquid medium is used to enrich *Microlunatus phosphovorus* and is incubated at 25°C with gentle shaking.

The isolation procedure of *Microlunatus aurantiacus* from a soil sample includes an additional pre-incubation. Prior to spreading on agar plates, a soil sample dried at room temperature is suspended in a phosphate buffer solution (pH 7.0) containing 0.1% sodium cholate and incubated for 1 h at 45°C with vigorous shaking in order to eliminate fast-growing bacteria and disperse soil aggregates. The glycerol-asparagine based agar medium (ISP5 medium; Shirling and Gottlieb, 1966) is used as the isolation medium, and inoculated agar plates are incubated at 28°C for 21–30 d. To enrich this species, the modified ISP2 agar medium containing the following ingredients (per liter) is used: 4 g of glucose, 4 g of yeast extract, 5 g of malt extract, and a vitamin/amino acid mixture (1 mg of vitamin B_1, 1 mg of vitamin B_2, 1 mg of vitamin B_6, 1 mg of biotin, 1 mg of nicotinic acid, 1 mg of phenylalanine, 0.3 g of alanine); pH 7.2.

To isolate *Microlunatus ginsengisoli* and *Microlunatus panaciterrae*, MR2A agar medium is used. The MR2A agar medium is composed of (per liter): 0.25 g of tryptone, 0.25 g of peptone, 0.25 g of yeast extract, 0.125 g of malt extract, 0.125 g of beef extract, 0.25 g of Casamino acids, 0.25 g of soytone, 0.5 g of glucose, 0.3 g of soluble starch, 0.2 g of xylan, 0.3 g of sodium pyruvate, 0.3 g of K_2HPO_4, 0.05 g of $MgSO_4$, 0.05 g of $CaCl_2$, and 15 g of agar. These species can be maintained using standard R2A agar and nutrient agar as well as the modified R2A agar at 30°C.

Microlunatus soli and *Microlunatus parietis* can be cultured on R2A agar and nutrient agar at 30°C.

Maintenance procedures

A liquid culture of the type species, *Microlunatus phosphovorus*, retains viability for several months at room temperature in the dark. Long-term preservation at −80°C is possible in the presence of 10% (w/v) glycerol. Freeze-drying is also available with a suitable protective matrix.

Microlunatus ginsengisoli, *Microlunatus aurantiacus*, and *Microlunatus panaciterrae* can be preserved at −70°C in a 20% (w/v) glycerol suspension. Long-term preservation of *Microlunatus soli* and *Microlunatus parietis* is feasible by storage in 20% (v/v) glycerol stock and by lyophilization.

Differentiation of the genus *Microlunatus* from other genera

The genus *Microlunatus* can be differentiated clearly from other genera within the family *Propionibacteriaceae* by 16S rRNA gene sequence analysis (Figure 242). All species belonging to the genus *Microlunatus* are closely related to each other (the

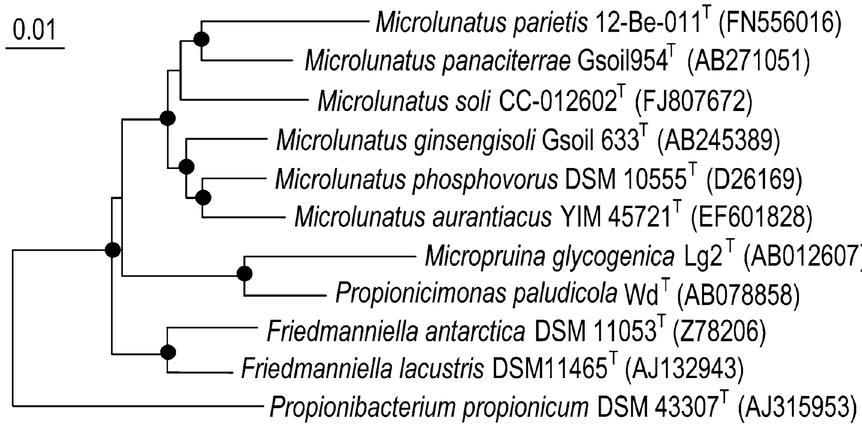

FIGURE 242. Phylogenetic relationships of the species of the genus *Microlunatus* based on 16S rRNA gene sequences constructed using the neighbor joining method. The EMBL/GenBank accession number of each sequence is indicated in parentheses. A bootstrap value (1000 replications) greater than 60% is shown as a closed circle at each branch point. The scale bar shows substitutions per 100 nucleotide positions.

sequence similarities among them are more than ~96%) and form a coherent cluster in the phylogenetic tree.

The related genera are *Micropruina*, *Propionicimonas*, and *Friedmanniella*, but all the members in the genus *Microlunatus* are phylogenetically distant from any species belonging to these related genera. All species in the genus *Microlunatus* and the related genera share the following common features in their phenotype: all are Gram-stain-positive, nonsporeforming, nonmotile cocci; contain $C_{15:0}$ anteiso as a main fatty acid component; and have menaquinone-9(H_4) as the major quinone. However, they can be differentiated from each other by comprehensive comparison of phenotypic characteristics such as their peptidoglycan types, nutritional profiles, and genomic G+C content.

Taxonomic comments

The type species of the genus, *Microlunatus phosphovorus*, was first described in 1995 with a proposal of the genus *Microlunatus* (Nakamura et al., 1995). The species was found in activated sludge in the wastewater treatment process. Since the first description, no species was newly proposed in this genus for more than ten years. From 2007 to 2008, three new bacteria belonging to the genus *Microlunatus* were found and proposed as new species. These new species, *Microlunatus ginsengisoli, Microlunatus aurantiacus*, and *Microlunatus panaciterrae*, were all isolated from soil, revealing that *Microlunatus* species inhabit not only the hydrosphere but also the lithosphere (An et al., 2008; Cui et al., 2007; Wang et al., 2008). In addition to these species, *Microlunatus soli* and *Microlunatus parietis* were newly isolated from the spawn of an edible mushroom, *Agaricus brasiliensis*, and an indoor wall, respectively. They were classified in the genus *Microlunatus* in 2010 (Kämpfer et al., 2010a, 2010b). At present, the genus *Microlunatus* consists of the following six species: *Microlunatus phosphovorus*, *Microlunatus aurantiacus*, *Microlunatus ginsengisoli*, *Microlunatus panaciterrae*, *Microlunatus parietis*, and *Microlunatus soli.*

List of species of the genus *Microlunatus*

1. **Microlunatus phosphovorus** Nakamura, Hiraishi, Yoshimi, Kawaharazaki, Masuda and Kamagata 1995, 21[VP]

phos.pho′vo.rus. L. n. *phosphorus* (from Gr. n. *phōsphoros* the light-bringer), the morning-star and, in chemistry, phosphorus; N.L. adj. *vorus* devouring; N.L. masc. adj. *phosphovorus* intended to mean phosphorus-accumulating microorganism.

The cells have a diameter of 0.8–2.0 µm and occur singly, in pairs, and occasionally in clusters. Often have a cell-wall structure in the middle of the cell and are hemispherical, especially at the stationary growth phase. The doubling time is about 13 h in a liquid medium. The colonies are circular (diameters, 0.5–1 mm), smooth, convex, and cream colored at the early stage of growth. After 10–14 d of incubation, the colonies are 1–2 mm in diameter and yellowish. Oxidase is positive but weak. The cells reduce nitrate to nitrite but do not reduce nitrite to nitrogen. The species has high phosphate-accumulating activity in the absence of any carbon substrate in the medium when it is exposed to exogenous phosphate under aerobic conditions (an intracellular phosphorus content sometimes increases more than 10% on a dry cell weight). The cells utilize glucose, mannose, galactose, xylose, arabinose, sucrose, maltose, cellobiose, trehalose, and melibiose, but not lactose. Starch is utilized, but glycogen is not utilized. Sugar alcohols such as inositol, dulcitol, and mannitol are utilized. Alcohols like methanol, ethanol, propanol, and glycerol are not utilized. Pyruvate is utilized, and acetate is utilized slowly. Growth occurs at 5–35°C with an optimum growth temperature of 25°C. The optimum pH is 7.0.

Source: sludge operating under alternating anaerobic and aerobic conditions.

DNA G+C content (mol%): 67.9 (HPLC).

Type strain: NM-1, ATCC 700054, CIP 104466, DSM 10555, HAMBI 2303, JCM 9379, NBRC 101784, VKM Ac-1990.

Sequence accession no. (16S rRNA gene): D26169, Z78207.

2. **Microlunatus aurantiacus** Wang, Cai, Zhi, Zhang, Tang, Xu, Cui and Li 2008, 1875[VP]

au.ran.ti.a′cus. N.L. masc. adj. *aurantiacus* orange-colored, referring to the orange color of the colonies.

Cells are cocci, 0.9–1.3 μm in diameter. Colonies are very small (~0.5–2.0 mm in diameter after incubation for 4 d on ISP2 agar medium at 28°C), smooth, circular, convex, and orange–yellow. Growth occurs at 15–37°C and pH 7.0–7.5. Growth occurs in the absence of NaCl. Oxidase-negative. Nitrate is reduced under anaerobic conditions. Cells show a weak phosphate-accumulating activity. Acid is produced from amygdalin, fructose, D-glucose, lactose, maltose, mannose, melibiose, raffinose, sucrose, trehalose, xylitol, and L-xylose. Utilizes arbutin, fructose, D-adonitol, esculin, alanine, amygdalin, fumarate, inulin, D-mannose, methyl α-D-galactoside, methyl β-D-galactoside, methyl α-D-glucoside, raffinose, D-ribose, salicin, D-sorbitol, starch, sucrose, trehalose, Tween 20, urea, xylitol, DL-xylose, adenine, asparagine, arginine, glutamate, histidine, hypoxanthine, threonine, tyrosine, and xanthine as sole carbon sources. The phospholipid pattern consists of diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol.

Source: a soil sample collected from the rhizosphere of *Taxus chinensis* in Yunnan Province, China.

DNA G+C content (mol%): 70.9 (HPLC).

Type strain: YIM 45721, CCTCC AB 206067, DSM 18424.

Sequence accession no. (16S rRNA gene): EF601828.

3. **Microlunatus ginsengisoli** Cui, Im, Yin, Yang and Lee 2007, 715[VP]

gin.seng.i.so′li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of soil of a ginseng field, the source of the type strain.

Cells are 0.5–0.8 μm in diameter. Colonies are very small, smooth, circular, non-glossy, yellowish, and convex. Grows well at 20–30°C and at pH 5.5–8.5. Grows on nutrient agar but not MacConkey agar. Growth on MR2A agar occurs both in the absence of NaCl and in the presence of 4.0% (w/v) NaCl. No growth at 6% NaCl and higher. Oxidase-negative. Nitrate, as a nitrogen source, is reduced under aerobic conditions, but not under anaerobic conditions. β-Galactosidase and gelatinase activities and the Voges–Proskauer reaction are positive (API 20E). The following compounds are utilized as sole carbon sources: D-glucose, L-rhamnose, D-fructose, D-lyxose, D-ribose, L-xylose, propionate, valerate, fumarate, salicin, lactate, malate, tartrate, sucrose, D-trehalose, D-raffinose, gluconate, D-adonitol, D-sorbitol, xylitol, amygdalin, inulin, dextran, alanine, asparagine, aspartate, histidine, phenylalanine, praline, and tyrosine.

Source: soil from a ginseng field in Pocheon province, South Korea.

DNA G+C content (mol%): 69.8 (HPLC).

Type strain: Gsoil 633, DSM 17942, JCM15306, KCTC 13940.

Sequence accession no. (16S rRNA gene): AB245389.

4. **Microlunatus panaciterrae** An, Im and Yoon 2008, 2736[VP]

pa.na.ci.ter′ra.e. N.L. n. *Panax -acis* scientific name for ginseng; L. n. *terra* soil; N.L. gen. n. *panaciterrae* of soil of a ginseng field.

Cells are cocci, 0.3–0.7 μm in diameter. Colonies grown on R2A agar for 5 d are smooth, circular, non-glossy, yellowish, convex, and 1–2 mm in diameter. Grows well at 20–30°C and at pH 5.0–9.0. Grows on nutrient agar, but not on MacConkey agar or trypticase soy agar. Growth on R2A agar occurs both in the absence of NaCl and in the presence of 5.0% (w/v) NaCl but not at 6.0% NaCl. Oxidase-positive. Anaerobic growth does not occur. Nitrate is not reduced under anaerobic condition. Acid is produced from amygdalin, L-arabinose, D-glucose, melibiose, and L-rhamnose. β-Galactosidase, β-glucosidase, gelatinase, and the Voges–Proskauer reaction are positive (API20E). The following compounds are utilized as sole carbon sources: D-arabinose, citrate, D-fucose, L-fucose, D-glucose, lactate, maltose, D-mannose, melibiose, L-rhamnose, D-ribose, salicin, D-sorbitol, and sucrose. Starch is degraded. The polar lipids detected are phosphatidylethanolamine, diphosphatidylglycerol, and phosphatidylglycerol.

Source: soil from a ginseng field in Pocheon Province, South Korea.

DNA G+C content (mol%): 65.1 (HPLC).

Type strain: Gsoil 954, DSM 18662, KCTC 13058.

Sequence accession no. (16S rRNA gene): AB271051.

5. **Microlunatus parietis** Kämpfer, Schäfer, Lodders and Martin 2010a, 2422[VP]

pa.ri′e.tis. L. gen. n. *parietis* of the wall of a house.

Cells are rod-shaped and cocci. Good growth occurs on R2A agar, tryptone soy agar, M79 (modified Letheen Broth) agar, and nutrient agar at 25–30°C. Utilizes arbutin, cellobiose, D-fructose, D-galactose, sucrose, salicin, trehalose, D-xylose, adonitol, *myo*-inositol, maltitol, and D-mannitol. Weakly utilizes *N*-acetyl-D-glucosamine. The polar lipid profile mainly consists of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, two unknown phospholipids, and one unknown glycolipid.

Source: an indoor wall in Berlin, Germany.

DNA G+C content (mol%): not determined.

Type strain: 12-Be-011, CCM 7636, DSM 22083.

Sequence accession no. (16S rRNA gene): FN556016.

6. **Microlunatus soli** Kämpfer, Young, Busse, Chu, Schumann, Arun, Shen and Rekha 2010b, 827[VP]

so′li. L. gen. n. *soli* of soil, the source of the type strain.

Cocci, 1.0–1.5 μm in diameter. Good growth occurs on R2A agar and nutrient agar at 25–30°C. Oxidase-positive. Utilizes *N*-acetyl-D-glucosamine, arbutin, cellobiose, D-fructose, D-galactose, sucrose, salicin, trehalose, D-xylose, adonitol, *myo*-inositol, maltitol, D-mannitol, acetate, and propionate. Weakly utilizes L-malate, L-histidine, L-proline, and L-serine. Cell-wall peptidoglycan is A3γ′ containing LL-diaminopimelic acid and glycine. The polyamine pattern is composed of spermidine and spermine as major compounds. Major polar lipids are phosphatidylglycerol and an unknown phospholipid followed by diphosphatidylglycerol, some unknown phospholipids, and an unknown glycolipid. A significant amount of an unsaturated fatty acid, $C_{18:1}$ ω7*c*, is the major cellular fatty acid. A small amount of $C_{14:0}$ 2-OH is also found.

Source: spawn of the edible mushroom *Agaricus brasiliensis*.

DNA G+C content (mol%): not determined.

Type strain: CC-12602, CCM7685, DSM21800.

Sequence accession no. (16S rRNA gene): FJ807672.

Genus VIII. **Micropruina** Shintani, Liu, Hanada, Kamagata, Miyaoka, Suzuki and Nakamura, 2000, 205[VP]

Lyudmila I. Evtushenko

Mi.cro.prui′na. Gr. adj. *mikros* small, fine; L. fem. n. *pruina* hoarfrost; N.L. fem. n. *Micropruina* fine hoarfrost.

Spherical cells, 0.5–2.2 µm in diameter (mostly about 1.0 µm) that are arranged in pairs, short chains, or clusters. Nonmotile. Nonsporeforming. **Gram-stain-positive**. Capsules are produced. **Chemo-organotroph, with a respiratory type of metabolism. Catalase and oxidase activities are positive**. Nitrate is used as an electron acceptor under anaerobic conditions; no production of nitrogen gas. The only known species, *Micropruina glycogenica*, is a slowly growing organism. Carbohydrates, sugar alcohols, carbonic acids, and amino acids are utilized as carbon sources; oxidative acid production occurs. **Capable of accumulating cellular glycogen**. Mesophilic and neutrophilic; growth occurs at 20–35°C and at pH 6–8. The optimum temperature and pH are 30°C and 7.0.

The cell-wall peptidoglycan contains *meso*-diaminopimelic acid (*meso*-A_2pm). Menaquinones are the only detected respiratory quinines; the tetrahydrogenated menaquinone with nine isoprene units, **MK-9(H_4), is the predominant** component. The major cellular fatty acids are $C_{15:0}$ anteiso, $C_{14:0}$ iso, $C_{16:0}$ iso, and $C_{16:0}$. No tuberculostearic or other 10-methyl branched acids are detected. Mycolic acids are absent.

The type species was isolated from an anaerobic-aerobic sequential batch biofilter reactor. No evidence of pathogenic properties.

DNA G+C content (mol%): 70.5.

Type species: **Micropruina glycogenica** Shintani, Liu, Hanada, Kamagata, Miyaoka, Suzuki and Nakamura 2000, 206[VP].

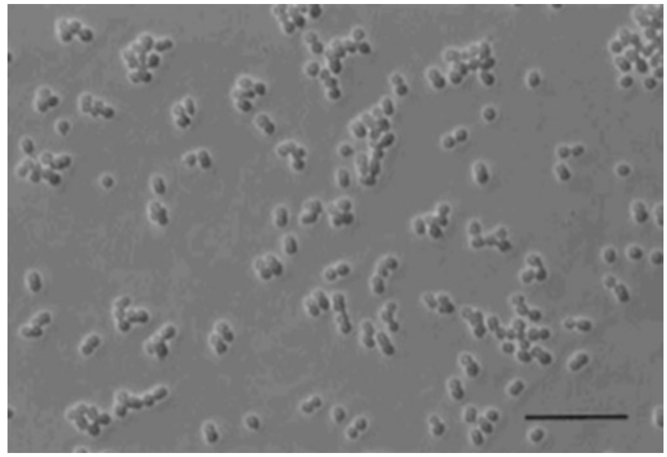

FIGURE 243. Phase-contrast photomicrograph of *Micropruina glycogenica* cells grown in NM-1 medium at 30°C. Bar = 10 µm. (Reproduced with permission from Shintani et al., 2000; Int. J. Syst. Evol. Microbiol. *50*: 201–207).

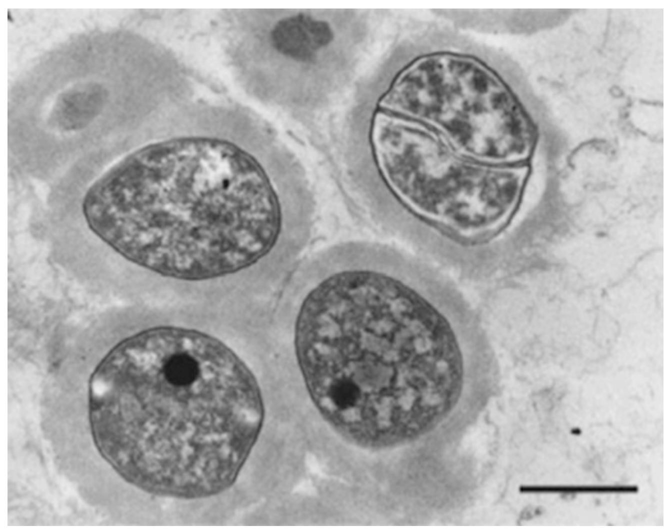

FIGURE 244. Transmission electron micrograph of *Micropruina glycogenica* cells with surrounding capsules. Cells were grown in NM-1 medium with a gentle shaking at 30°C. Bar = 1 µm. (Reproduced with permission from Shintani et al., 2000; Int. J. Syst. Evol. Microbiol. *50*: 201–207).

Further descriptive information

The growing cells divide at the middle by a septum to form pairs of cells which may be arranged in short chains, packets, or clusters (Figure 243 and Figure 244). Cells are individually surrounded by a capsule. The cell-wall structure is typical of Gram-stain-positive bacteria; Gram-stain-positive.

Little information is available on the habitats and ecology of organisms of the genus *Micropruina*. The type strain of *Micropruina glycogenica* was isolated from an anaerobic-aerobic sequential batch biofilter reactor exhibiting a biological phosphorus removal activity. However, neither orthophosphate uptake activity nor accumulation of intracellular polyphosphate has been detected in this bacterium by Neisser staining. Two organisms closely related to *Micropruina glycogenica* (>98% 16S rRNA gene sequence similarity) have been revealed in activated sludge and in sea water (GenBank accession numbers EU104262 and FJ545597, respectively).

Enrichment and isolation procedures

The *Microlunatus* agar medium (NM-1) containing glucose (0.5 g), peptone (0.5 g), monosodium glutamate (0.5 g), yeast extract (0.5 g), KH_2PO_4 (0.44 g), $(NH_4)_2SO_4$ (0.1 g), $MgSO_4 \cdot 7H_2O$ (0.1 g), agar (15 g), and 1 liter of distilled water (final pH, 7.0) (Nakamura et al., 1995) was used to isolate the type strain as described by Liu et al. (1997).

Maintenance procedures

Long-term conservation is achieved by freeze-drying and in liquid nitrogen.

Differentiation of the genus *Micropruina* from related genera

Tables 206, 208, and 212 lists characteristics differentiating *Micropruina* from the other genera of the family *Propionibacteriaceae*. Coccoid cells, along with the positive catalase and oxidase reactions and the presence of the predominant menaquinone MK-9(H_4), are the most salient characteristics that differentiate *Micropruina* from the phylogenetically closest genera *Propionicicella* and *Propionicimonas*. The extent of growth with (or without)

oxygen may also be used for the purposes of delineating *Micropruina* from the facultativelly anaerobic *Propionicicella* and *Propionicimonas*. The *meso*-A_2pm isomer in the cell-wall peptidoglycan readily differentiates *Micropruina* from the phylogenetically close genera of coccoid bacteria which have LL-A_2pm as the diagnostic diamino acid.

Taxonomic comments

On the basis of 16S rRNA gene analysis, *Micropruina glycogenica* was originally shown to form a separate phylogenetic cluster with the genera *Microlunatus* and *Friedmanniella*, which was loosely associated with a cluster encompassing *Nocardioides* and closely related genera of the family *Nocardioidaceae* (Shintani et al., 2000). Further phylogenetic analysis with the extended selection of related sequences led Stackebrandt and Schaal (2006a) to the conclusion that the genus *Micropruina*, along with *Microlunatus* and *Friedmanniella*, should be placed in the family *Propionibacteriaceae*.

List of species of the genus *Micropruina*

1. **Micropruina glycogenica** Shintani, Liu, Hanada, Kamagata, Miyaoka, Suzuki and Nakamura 2000, 206[VP]

gly.co.ge.ni′ca. N.L. n. *glycogenum* glycogen; L. fem. suff. *-ica* suffix used with the sense of pertaining to; N.L. fem. adj. *glycogenica* referring to the ability to accumulate glycogen.

Morphological and general phenotypic characteristics of the species are the same as described for the genus. Punctuated nonpigmented colonies are formed after 2–3 weeks on NM-1 agar medium. Large amount (up to 8.4% dry wt) of intracellular glycogen is accumulated as a storage material under aerobic and anaerobic conditions.

Aerobic growth in the liquid NM-1 medium is very slow. The doubling time is approximately 12.6 h at 30°C (the optimum growth temperature). The temperature range for growth is 20–35°C; growth is not observed below 16°C or above 37°C. Tolerates NaCl up to 3.0% (w/v). The pH range for growth was 6–8, with no growth at pH 5 and 9.

Reduces nitrate to nitrite under anaerobic conditions, but formation of nitrogen gas is not observable. The following carbon sources are utilized aerobically as determined using the Biolog system: glucose, arabinose, cellobiose, galactose, lactose, maltose, mannose, melibiose, sucrose, xylose, inositol, mannitol, acetate, propionate, pyruvate, succinate, alanine, arginine, and histidine. Trehalose, dulcitol, ethanol, glycerol, methanol, propanol, malate, asparagine, glutamate, and glutamine are not utilized. Starch and glycogen are hydrolyzed.

The cellular fatty acids of the type strain include $C_{15:0}$ anteiso (37.1%), $C_{16:0}$ (12.9%), $C_{14:0}$ iso (14.1%), $C_{16:0}$ iso (10.8%), $C_{15:0}$ iso (5.9%), $C_{18:0}$ (4.6%), $C_{14:0}$ (3.7%), and $C_{15:0}$ iso (2.2%).

Source: an anaerobic-aerobic sequential batch biofilter reactor.

DNA G+C content (mol%): 70.5 (HPLC).

Type strain: strain Lg2, DSM 15918, JCM 10248.

Sequence accession no. (16S rRNA gene): AB012607.

Genus IX. **Propionicicella** Bae, Moe, Yan, Tiago, da Costa and Rainey 2006a, 2026[VP]

The Editorial Board

Pro.pi.o.ni.ci.cel′la. N.L. n. *acidum propionicum* propionic acid; L. fem. n. *cella* a storeroom, chamber, and in biology, a cell; N.L. fem. n. *Propionicicella* propionic-acid-producing cells.

Nonsporeforming rods, (0.5 × 1.0–2.5 µm). **Gram-stain-positive**. Nonmotile. **Facultative anaerobe**. Temperature range for growth 15–37°C, pH range 4.5–8.5, NaCl tolerance 0–4%. The peptidoglycan type is A1γ with *meso*-diaminopimelic (*meso*-DAP) in the cell wall. MK-9 is the major menaquinone. Propionate and acetate are produced when grown anaerobically with glucose.

DNA G+C content (mol%): 69.9.

Type species: **Propionicicella superfundia** Bae, Moe, Yan, Tiago, da Costa and Rainey 2006a, 2026[VP].

Further descriptive information

Major fatty acids are $C_{15:0}$ (54.3%), $C_{15:0}$ (16.3%), $C_{16:0}$ iso (12.8%), $C_{17:0}$ anteiso (5.4%), $C_{14:0}$ iso (5.3%), $C_{17:0}$ (2.9%) and $C_{16:0}$ (1.1%).

Phylogenetic analysis of the 16S rRNA gene suggests that the genus is affilitiated with the family *Propionibacteriaceae*. The closest phylogenetic neighbor is *Propionicimonas* sp. F6 (97.3% sequence similarity, accession AY570689), which was isolated from production waters of a low-temperature, biodegraded oil reservoir (Grabowski et al., 2005). Nearest type strains are *Propionicimonas paludicola* (accession no. AB078858; Akasaka et al., 2003b) and *Micropruina glycogenica* (accession no. AB012607; Shintani et al., 2000), 97.5% and 95.4%, respectively. An environmental clone with high 16S rRNA gene sequence similarity have been detected colonizing the gut epithelium (97.5%, accession no. AB198497) (Nakajima et al., 2005).

Enrichment and isolation procedures

Strain BL-10[T] was isolated from groundwater samples collected from well W-1024-1 located in the dense non-aqueous-phase liquid (DNAPL) source zone at the Brooklawn portion of the Petro-Processors of Louisiana, Inc. (PPI) EPA Superfund Site, located approximately 10 miles north of Baton Rouge, LA (USA). Sterile, 1-l glass sample collection bottles were filled with groundwater, leaving little or no headspace, and placed on ice during transport to the laboratory (approx. 1 h). Serial diluents (anaerobically in 100 mM potassium phosphate buffer, pH 7.0) were transferred onto Columbia Anaerobic Sheep Blood agar plates (CASB, BBL) and incubated anaerobically under an atmosphere of 90% N_2, 5% CO_2, and 5% H_2 at 30°C for up to 5 weeks.

Maintenance procedures

Strains are maintained anaerobically on CASB or PYG media (Akasaka et al., 2003b). Stock cultures are maintained as a 15% (v/v) glycerol and 5% (v/v) dimethylsulfoxide suspension at −80°C.

Differentiation of the genus *Propionicicella* from closely related genera

Facultative anaerobic growth, rod-shaped morphology, and predominant menaquinone MK-9 differentiate *Propionicicella* from phylogenetically related genera *Ponticoccus*, *Friedmanniella*, *Microlunatus*, and *Micropruina*, which are all aerobic cocci with MK-9(H_4) as the predominant menaquinone. Predominant menaquinones MK-9(H_4) and MK-10(H_4) distinguishes *Propionicimonas* from *Propionicicella*. *Ponticoccus*, *Friedmanniella*, *Microlunatus*, and *Micropruina* are catalase-positive, and *Propionicicella* is catalase-negative. *Ponticoccus* and *Micropruina* reduce nitrate and *Propionicicella* does not.

List of species of the genus *Propionicicella*

1. **Propionicicella superfundia** Bae, Moe, Yan, Tiago, da Costa and Rainey 2006a, 2026[VP]

   su.per.fun′di.a. L. prep. *super* above/on top; L. masc. n. *fundus* land owned by someone; L. adjectival ending *-ius -ia -ium* indicating the meaning of "belonging to"; N.L. fem. adj. *superfundia* referring to land designated as a US Environmental Protection Agency Superfund Site.

   Colonies are white, circular, convex, smooth and 2–3 mm in diameter on PYG agar. Growth occurs at mesophilic temperatures and pH 4.5 and 8.5, with optima at 30°C and pH 6.5. NaCl tolerance ≤ 4.0% (w/v). Catalase- and oxidase-negative. Nitrate is not reduced. Glucose fermentation products are formic acid, acetic acid, propionic acid, and succinic. Utilizes adonitol, erythritol, fructose, glucose, glycerin, lactate, maltose, mannitol, mannose, pyruvate, sorbitol, sucrose, and xylose. Does not utilize acetate, arabinose crystalline cellulose, dulcitol, ethanol, fucose, galactose, lactose, malate, meliobiose, methanol, raffinose, rhamnose, starch, succinate, and fumarate. Rapid ID 32A kits (bioMérieux) detects α-glucosidase, β-glucosidase, glycine arylamidase, histidine arylamidase, proline arylamidase, leucyl glycine arylamidase, phenylalanine arylamidase, leucine arylamidase, and alanine arylamidase, but not glutamyl glutamic acid arylamidase, alkaline phosphatase, α-fucosidase, glutaminc acid decarboxylase, arginine dehydrogenase, urease, α-galactosidase, and β-galactosidase. Fermentation occurs in the presence of 0–9.8 mM and 0–5.9 mM 1,2-dichloroethane and 1,1,2-trichloroethane, respectively.

   For all other characteristics, refer to the genus description.

   DNA G+C content (mol%): 69.9 (HPLC).

   Type strain: BL-10, ATCC BAA-1218, LMG 23096.

   Sequence accession no. (16S rRNA gene): DQ176646.

Genus X. **Propionicimonas** Akasaka, Ueki, Hanada, Kamagata and Ueki 2003b, 1996[VP]

Atsuko Ueki, Hiroshi Akasaka and Katuji Ueki

Pro.pio.ni.ci.mo′nas. N.L. n. *acidum propionicum* propionic acid; L. fem. n. *monas* a unit, monad; N.L. fem. n. *Propionicimonas* propionic acid-producing monad.

Irregular, often slightly curved rods. **Gram-stain-positive**. Endospores are not produced. Nonmotile. **Facultatively anaerobic**. **Chemo-organotrophic**. Negative for oxidase, catalase, and nitrate reduction. Mesophilic. **In the presence of an excess amount of cobalamin, acetate and propionate are produced anaerobically as major fermentation products from glucose**. Cell-wall peptidoglycan contains ***meso*-diaminopimelic acid (DAP)**, and major cellular fatty acids are **$C_{13:0}$, $C_{15:0}$ anteiso, and $C_{15:0}$**. The major respiratory quinones are **MK-9(H_4) and MK-10(H_4)**. Based on 16S rRNA gene sequences, species in the genera *Micropruina*, *Microlunatus*, and *Friedmanniella* in the *Nocardioidaceae* are the most closely related to those of *Propionicimonas*. Isolated from rice plant residue (straw and roots) in irrigated rice field soil in Japan.

DNA G+C content (mol%): 68.7 (HPLC).

Type species: **Propionicimonas paludicola** Akasaka, Ueki, Hanada, Kamagata and Ueki 2003b, 1996[VP].

Further descriptive information

The following information is based on the description of strains of *Propionicimonas paludicola*. Grows weakly under aerobic conditions; much better growth occurs anaerobically. Colonies are white and 2–3 mm in diameter after 2–3 d of anaerobic cultivation. Growth rates in PYG medium (Holdeman et al., 1977) are very slow for most strains, but growth, as well as propionate production, is stimulated significantly by the addition of cobalamin to the medium. Some strains do grow well in PYG medium without cobalamin and produce substantial amounts of acetate and propionate; however, their other phenotypic and phylogenetic characteristics are almost identical to those of strains that do require cobalamin. The cell-wall structure is typical of Gram-stain-positive bacteria. Intracellular storage compounds in the cells are shown as electron-translucent regions by electron microscopy.

Isolation procedures

The plant residue samples collected from irrigated rice field soil are washed with anoxic diluent, cut to pieces, and homogenized using a Waring blender under N_2 gas. The homogenized samples are diluted consecutively with anoxic diluent and inoculated into the medium by the anaerobic roll-tube method (Holdeman et al., 1977). Colonies formed in the roll tubes during incubation for 2 weeks are picked up and strains can be purified by repeating the roll-tube method (Akasaka et al., 2003a). Strains can also often be isolated from roots of living rice plants of the same rice field.

TABLE 211. Differential characteristics of the genus *Propionicimonas* and closely related genera[a,b]

Characteristic	*Propionicimonas*	*Micropruina*	*Microlunatus*	*Friedmanniella*
Source	Plant residue in paddy soil	Activated sludge reactor	Activated sludge reactor	Antarctic sandstone
Cell shape	Irregular rods	Cocci (single, pair, or packet)	Cocci (single or pair)	Cocci (arranged in packet)
Cell size (μm)	0.4–0.5 × 1.4–2.2	0.5–2.2	0.8–2.0	0.5–2.2
Color of colony	White	White	Cream	Orange
Optimum growth temperature (°C)	35	30	25–30	20–26
O_2 requirement	Facultative anaerobe	Aerobe	Aerobe	Aerobe
Oxidase	−	+	+	−
Catalase	−	+	+	+
Nitrate reduction	−	+	+	−
Acid production from glucose	+	+	+	−
DNA G+C content (mol%)	67.4–68.7	70.5	67.9	69–74
Major quinone	MK-9(H_4), MK-10(H_4)	MK-9(H_4)	MK-9(H_4)	MK-9(H_4)
Major cellular fatty acids	$C_{13:0}$, $C_{15:0}$ anteiso, $C_{15:0}$	$C_{14:0}$ iso, $C_{15:0}$ anteiso, $C_{16:0}$ iso, $C_{16:0}$	$C_{15:0}$ iso, $C_{15:0}$ anteiso	$C_{15:0}$ iso, $C_{15:0}$ anteiso
Peptidoglycan	*meso*-DAP	*meso*-DAP	LL-DAP	LL-DAP

[a]Symbols: +, >85% positive; -, 0–15% positive.

[b]Data from Shintani et al. (2000); Nakamura et al. (1995); Schumann et al. (1997); Maszenan et al. (1999a); Lawson et al. (2000c).

Maintenance procedures

The strains are cultivated anaerobically at 30°C using PY medium (Holdeman et al., 1977) as a basal medium with oxygen-free N_2/CO_2 (95:5) mixed gas as headspace closed with butyl-rubber stoppers. PY medium supplemented with (per litre) 0.25 g each of glucose, cellobiose, maltose, and soluble starch, as well as 50 ml plant residue extract (RE) and 15 g agar (pH 7.3) is used for maintenance in agar slants. Rice plant residue collected from irrigated rice field soil during the flooding period is autoclaved (120°C for 30 min) with a fivefold amount (wet weight basis) of deionized H_2O, and the supernatant obtained after centrifugation is used as RE for the provision of growth factors (Akasaka et al., 2003a). RE prepared as above contains 3–5 μg/l cobalamin (Akasaka et al., 2004). Cobalamin itself is not usually added to the medium for slant cultures to avoid excess growth. Anaerobic slant cultures kept at 4°C can remain viable for at least several months, or the slant cultures can be maintained at −70°C without transfer for more than 5 years.

Taxonomic comments

Based on 16S rRNA gene sequences, the species forms a cluster close to the genera *Micropruina* (Shintani et al., 2000), *Microlunatus* (Nakamura et al., 1995), and *Friedmanniella* (Schumann et al., 1997) in the *Actinobacteria*. The closest relative is *Micropruina glycogenica* (Shintani et al., 2000), with sequence similarity of 95.8%. The closest relative to the type strain of *Propionicimonas paludicola* is an environmental clone, SJA-181, which is derived from an anaerobic microbial consortium in a trichlorobenzene-transforming bioreactor (16S rRNA gene sequence similarity of 98.3%). *Propionicimonas paludicola* is only distantly related to the propionate-producing species *Propionibacterium propionicus* and *Propioniferax innocua* in the *Propionibacteriaceae*, with sequence similarities of 91.5–92.0% and 90.0%, respectively.

Differentiation of the genus *Propionicimonas* from other genera

Unlike *Propionicimonas paludicola*, all species in the closely related genera *Micropruina*, *Microlunatus*, and *Friedmanniella* have spherical cells, often arranged in packets. Related species are strictly aerobic and catalase-positive. Both *Micropruina* and *Microlunatus* species have oxidase and nitrate-reducing activities. Major cellular fatty acids of these relatives are $C_{14:0}$ iso, $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{16:0}$ in addition to $C_{15:0}$ anteiso. $C_{13:0}$ and $C_{15:0}$ fatty acids are absent or only present as minor components. All relatives also have MK-9(H_4) as a major respiratory quinone, but do not contain MK-10(H_4), which is found in *Propionicimonas paludicola* (Lawson et al., 2000c; Maszenan et al., 1999a; Nakamura et al., 1995; Schumann et al., 1997; Shintani et al., 2000). Among the close relatives, only *Micropruina* species has *meso*-DAP in the peptidoglycan of the cell wall (Shintani et al., 2000); species in other two genera have LL-DAP (Table 211).

List of species of the genus *Propionicimonas*

1. **Propionicimonas paludicola** Akasaka, Ueki, Hanada, Kamagata and Ueki 2003b, 1996

pa.lu.di′co.la. L. n. *palus -udis* a swamp, marsh; L. suff. *-cola* (from L. n. *incola*) inhabitant, dweller; N.L. masc. n. *paludicola* an inhabitant of swamps.

Cells are pleomorphic rods, frequently arranged in irregular V- or crescent-shapes, 1.8–2.0 × 0.4–0.5 μm. In the presence of excess amounts of cobalamin in the medium, all strains produce acetate and propionate in the molar ratio of 2:1, with small amounts of lactate and succinate, from

glucose; however, lactate production is predominant under cobalamin limitation for cobalamin-requiring strains. Optimal growth occurs at 35°C and pH 6.5. The species grows in the presence of up to 2.0% (w/v) NaCl. Acids are produced from arabinose, xylose, fructose, galactose, glucose, mannose, cellobiose, maltose, sucrose, trehalose, glycerol, and mannitol. Ribose and lactose are poorly utilized. Grows on pyruvate and lactate, and very weakly on malate, fumarate, and succinate. Does not utilize fucose, rhamnose, sorbose, melibiose, melezitose, raffinose, cellulose, glycogen, soluble starch, xylan, adonitol, dulcitol, erythritol, inositol, sorbitol, ethanol, methanol, or propanol. Other characteristics are as described for the genus.

Source: isolated from rice plant residue (straw and roots) in irrigated rice field soil in Japan.

DNA G+C content (mol%): 68.7 (HPLC).

Type strain: JCM 11033, DSM 15597.

Sequence accession no. (16S rRNA gene): AB078858.

Genus XI. **Propioniferax** Yokota, Tamura, Takeuchi, Weiss and Stackebrandt 1994, 581[VP]

Akira Yokota

Pro.pio.ni.fe′rax. N.L. n. *acidum propionicum* propionic acid; L. adj. *ferax* fertile; N.L. fem. n. *propioniferax* propionic acid-producing.

Cells are **Gram-stain-positive**, non-acid-fast, **nonmotile**, nonsporing, **pleomorphic rods**, appearing in clusters and V forms. **Facultatively anaerobic** but luxuriant growth occurs aerobically. Oxidase- and catalase-positive. Cell wall contains **LL-diaminopimelic acid**, arabinose, and mannose, but not galactose. Glycine forms the interpeptide bridge of peptidoglycan. Mycolic acids are not present. Major fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso. The major respiratory quinone is **MK-9(H_4)**.

DNA G+C content (mol%): 59–63 (T_m).

Type species: **Propioniferax innocua** Yokota, Tamura, Takeuchi, Weiss and Stackebrandt 1994, 581[VP].

Further descriptive information

Propionibacterium innocuum was proposed by Pitcher and Collins (1991) for a coryneform bacterium species containing LL-diaminopimelic acid (LL-A_2pm) in the cell wall. However, in contrast to other species of the genus *Propionibacterium* (Charfreitag et al., 1988; Cummins and Johnson, 1986), strains of *Propionibacterium innocuum* showed aerobic growth, did not require blood, serum, or Tween 80 for growth, and contained arabinose in cell-wall hydrolyzates. In addition, 16S rRNA analysis indicated that *Propionibacterium innocuum* was only remotely related to other members of the genus *Propionibacterium.* On the basis of physiological and chemotaxonomic characteristics, and a 16S rRNA gene sequence comparison, the species *Propionibacterium innocuum* was transferred from the genus *Propionibacterium* to a new genus, *Propioniferax*, as *Propioniferax innocua* by Yokota et al. (1994). The genus *Propioniferax* is a single species genus. Some characteristics in the original description of the genus by Yokota et al. (1994) were transferred to the species description. The genus *Propioniferax* is a member of the family *Propionibacteriaceae* within the order *Propionibacteriales* represented by the genus *Propionibacterium* Orla-Jensen 1909 (Figure 245).

Isolation and maintenance procedures

Strains of *Propioniferax innocua* originated from human skin, isolated from laboratories in Philadelphia (USA), Leiden (The Netherlands), and London (UK). Strains were routinely cultured aerobically on nutrient agar (Oxoid) at 37°C. Anaerobic growth on nutrient agar under an atmosphere of 95% H_2 and 5% CO_2 was much reduced. Cells grow well in CPY broth (casein peptone, 10 g; yeast extract, 5 g; and H_2O, 1 liter; pH 7.2) and tryptone soy broth (Difco) supplemented with 1% yeast extract.

Strains of the genus *Propioniferax* can be preserved by lyophilization suspended in 10% skim milk containing 1% monosodium glutamate, as well as by deep-freezing suspended in 10–20% glycerol solution at temperatures below −80°C.

Differentiation of the genus *Propioniferax* from other genera

The genus *Propioniferax* can be differentiated from closely related genera in the family *Propionibacteriaceae* based on chemotaxonomic and phylogenetic data, as shown in Table 212.

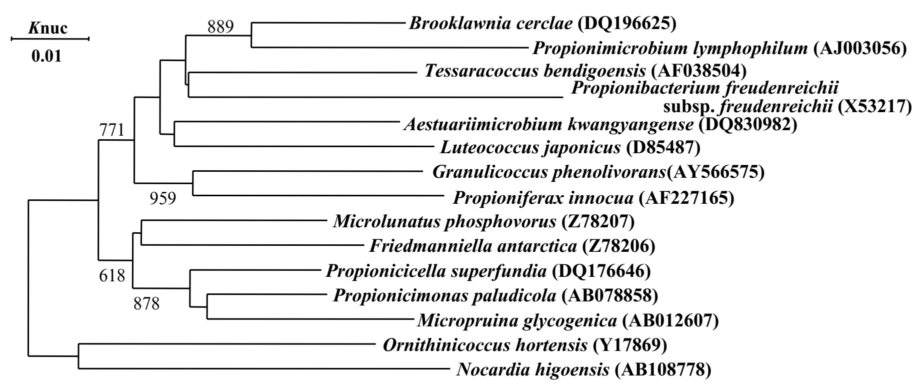

FIGURE 245. Phylogenetic relationships of the type strains of *Propioniferax* and named genera of the family *Propionibacteriaceae.* The neighbor-joining method was used for tree construction, 1000 bootstrap trees were generated and bootstrap values (>600; out of 1000 reiterations) are indicated at branch points.

List of species of the genus *Propioniferax*

1. **Propioniferax innocua** (Pitcher and Collins 1992) Yokota, Tamura, Takeuchi, Weiss and Stackebrandt 1994, 581^VP (*Propionibacterium innocuum* Pitcher and Collins 1992, 327)

in.noc′u.a. L. fem. adj. *innocua* harmless.

Cells are Gram-stain-positive, non-acid-fast, nonmotile, nonsporing, pleomorphic rods appearing in clusters and V forms. Colonies are white, shining, and convex to domed. The optimum growth temperature is approximately 37°C. Grows at 10 and 40°C. Facultatively anaerobic, but substantial growth occurs aerobically (colonies are approximately 0.5–3 mm in diameter after growth on nutrient or horse blood agar at 37°C for 2 d). Catalase- and oxidase-positive. The principal carboxylic acid produced from glucose is propionic acid. Glucose, sucrose, maltose, trehalose, fructose, mannose, and glycerol are fermented. Inositol, arabinose, adonitol, salicin, erythritol, mannitol, cellobiose, dulcitol, raffinose, lactose, sorbose, sorbitol, and rhamnose are not utilized, and galactose utilization is variable. Gelatin is hydrolyzed. Growth occurs in the presence of 7.5% NaCl, but not in 10% NaC1. Reduces nitrate. Hydrolyzes urea and starch. Growth is not stimulated by Tween 80, but Tween 80 is hydrolyzed. The following tests are negative: arginine dihydrolase, esculin hydrolysis, glutamate oxidation, arginine, lysine and ornithine decarboxylase, phenylalanine deaminase, citrate and malonate utilization, indole, H_2S, and decomposition of tyrosine and xanthine.

The cell wall contains LL-A_2pm, arabinose, and mannose, but not galactose. Major fatty acids are $C_{15:0}$ anteiso and $C_{15:0}$ iso. The major respiratory quinone is MK-9(H_4).

Source: human epidermal surface.

DNA G+C content (mol%): 59 to 63 (T_m).

Type strain: strain L60, ATCC 49929, CCUG 33480, DSM 8251, JCM 13395, LMG 16732, NCTC 11082.

Sequence accession no. (16S rRNA gene): AF227165.

Genus XII. **Propionimicrobium** Stackebrandt, Schumann, Schaal and Weiss 2002, 1926^VP

Erko Stackebrandt

Pro.pio.ni.mi.cro′bi.um. N.L. *acidum propionicum* propionic acid; N.L. neut. n. *microbium* (from Gr. adj. *mikros* small and Gr. n. *bios* life) a microbe; N.L. neut. n. *Propionimicrobium* propionic acid-producing microbe.

Pleomorphic rods, 0.5–0.8 × 1–2.5 µ, often diphtheroid or club-shaped. **Cells may be coccoid**. They may occur singly, in pairs or short chains, in V or Y configurations, or in clumps. Gram-stain-positive, nonmotile, nonsporeforming chemo-organotroph. **Anaerobic**. **Fermentation end products include propionic acid, acetic acid, succinic acid, iso-valeric acid, and lesser amounts of formic acid**. One out of two strains is catalase-positive. The major menaquinone is MK-9(H_4). **The peptidoglycan contains lysine and aspartic acid (Lys–Asp type)**. Major fatty acids are $C_{18:1}$ ω9*c*, $C_{15:0}$ anteiso, and $C_{16:0}$. The genus is a member of the family *Propionibacteriaceae* Delwiche (1957), emend. Stackebrandt, Rainey and Ward-Rainey (1997) *in* Rainey, Ward-Rainey and Stackebrandt (1997).

DNA G+C content (mol%): 53–56.

Type species: **Propionimicrobium lymphophilum** (Torrey 1916) Stackebrandt, Schumann, Schaal and Weiss 2002, 1926^VP ("*Bacillus lymphophilus*" Torrey 1916; *Propionibacterium lymphophilum* Johnson and Cummins 1972, 1057).

Further descriptive information

The exclusion of *Propionimicrobium lymphophilum* species from the genus *Propionibacterium* (Stackebrandt et al., 2002) was based upon phylogenetic evidence (Dasen et al., 1998) and information given by Cummins and Johnson (1986) based on the characterization of four strains (Holdeman et al., 1977; Johnson and Cummins, 1972). The description of the species is based on two strains, VIP 0202 and VIP 0383, which show 75% DNA similarity to one another. *Propionimicrobium lymphophilum* DSM 4309^T shares less than 91.8% sequence similarity with the *Propionibacterium* species (Dasen et al., 1998) which themselves show more than 93% similarity among each other. Depending upon the algorithm used, analysis of the 16S rRNA gene indicates that *Propionimicrobium lymphophilum* forms either the deepest branch of the genus *Propionibacterium* (Koussémon et al., 2001) (neighbor-joining program; Felsenstein, 1993), or branches among the other genera of the family *Propionibacteriaceae* (maximum-likelihood; Felsenstein, 1993) and distance matrix analyses (De Soete, 1983).

Enrichment and isolation procedures

The organism was first isolated by Torrey (1916) from lymph glands of a patient with Hodgkin's disease. Later, strains were isolated from urinary tract infections and from a mesenteric ganglion of a monkey inoculated with an unidentified "actinobacterium" isolate. Strains of the species have been reported to thrive in soil of rice paddy fields (Hayashi and Furusaka, 1980) and have been found in preparations of green olives (Cancho et al., 1980), but the identification of these strains did not include verification of the distinct cell-wall composition or the base composition of DNA (Cummins and Johnson, 1986).

Maintenance procedures

The organism can be maintained on modified Peptone-Yeast-Glucose agar (DSMZ medium 104; DSMZ (2001) or Columbia agar supplemented with 5% defibrinated sheep blood (Becton and Dickinson). Plates are sealed in plastic bags containing an Anerocult A (Merck) bag. Storage is in 20% (v/v) glycerol at −80°C or as lyophilized cultures.

Taxonomic comments

Strain VIP 0202 was originally described as "*Bacillus lymphophilus*" Torrey 1916, then as "*Corynebacterium lymphophilum*" (Torrey 1916) Eberson 1918 and as "*Mycobacterium lymphophilum*" (Torrey 1916) Krasil'nikov 1949, before it was included in a taxonomic study on coryneforms and propionibacteria (Johnson and Cummins, 1972). While membership of strain VIP 0202 in

Corynebacterium was excluded because of low DNA reassociation with members of this genus, it was tentatively classified as *Propionibacterium lymphophilum* based on its anaerobic growth and its ability to form propionic acid. *Propionibacterium lymphophilum* was included in the *Approved Lists of Bacterial Names* (Skerman et al., 1980), with reference to the publication of Johnson and Cummins (1972) and to the non-formal description of physiological and morphological properties by Holdeman et al. (1977) in the *Anaerobe Laboratory Manual of the Virginia Polytechnic Institute and State University*, Blacksburg, VA (VIP). The formal description of the species was made by Cummins and Johnson (1986) in their coverage of the genus *Propionibacterium* in *Bergey's Manual of Systematic Bacteriology*. Interestingly, both Holdeman et al. (1977) and Skerman et al. (1980) indicated strain VIP 7625B^T (=ATCC 27520^T) as the type strain, but neither Johnson and Cummins (1972), Holdeman et al. (1977), nor Cummins and Johnson (1986) refer to strain VIP 7625B^T but to strain VIP 0202. According to information obtained from the Technical Services of the ATCC in August 2001, strain ATCC 27520^T had originally been received as strain VIP 7625B^T.

In order to determine, whether strain VIP 7625B^T (=ATCC 27520^T = DSM 4309^T) was a subculture of strain VIP 0202, Stackebrandt et al. (2002) reinvestigated the base composition of DNA and the composition of peptidoglycan of strain DSM 4309^T, originally obtained for strain VIP 0202. The presence of lysine and the A4α (Lys–Asp) peptidoglycan type were confirmed as was the rather low base composition of DNA of 56 mol% G+C, which was slightly higher than the 53–54 mol% reported for strain VIP 0202.

Differentiation of the genus *Propionibacterium* from other genera

16S rRNA gene sequence analysis reveals the moderate 16S rRNA gene sequence relationship of strain DSM 4903^T to members of the genus *Propionibacterium* (>92%). The position of *Propionibacterium lymphophilum* outside the *Propionibacterium* cluster is not supported by high bootstrap values and its position changes with the algorithm applied. While it branches with *Tessarococcus bendigoensis* ACM 5119^T and *Propionibacterium propionicum* DSM 43307^T in the tree of Stackebrandt et al. (2002), it branches with *Luteococcus japonicus* IFO 12422^T in the tree of Dasen et al. (1998).

Physiologically the species can be differentiated from members of the genus *Propionibacterium* by a combination of results from esculin hydrolysis, indole production, and nitrate reduction, as well as by a combination of acid production from adonitol, erythritol, maltose, ribose, and L-sorbose, (Koussémon et al., 2001; Kusano et al., 1997). The composition of major fatty acids consisting of $C_{18:1}$ ω9*c*, $C_{15:0}$ anteiso, and $C_{16:0}$ differs significantly from those reported for *Propionibacterium* strains in which branched fatty acids (Moss et al., 1969) or ω-cyclohexane (Kusano et al., 1997) dominate.

List of species in the genus *Propionimicrobium*

1. **Propionimicrobium lymphophilum** (Torrey 1916) Stackebrandt, Schumann, Schaal and Weiss 2002, 1926^{VP} ("*Bacillus lymphophilus*" Torrey 1916; *Propionibacterium lymphophilum* Johnson and Cummins 1972, 1057)

lym.pho′phi.lum L. fem. n. *lympha* clear water and, in biology, lymph; N.L. neut. adj. *philum* (from Gr. neut. adj. *philon*), friend, loving; N.L. neut. adj. *lymphophilum*, lymph-loving.

Surface colonies on horse blood in 4 d are punctiform to 0.5 mm, circular, entire, convex to pulvinate, white, glistening, and smooth. Glucose cultures (24 h) are turbid, becoming clear, with a ropy sediment and a terminal pH of 5.4–5.7. Anaerobic, producing no growth on the agar surface when incubated aerobically, but growth develops in deep broth incubated aerobically. Acid production from adonitol, erythritol, fructose, glucose, maltose, and ribose, as well as from starch and inositol (reaction positive in 40–90% of strains). Acid is not formed from amygdalin, arabinose, cellobiose, dulcitol, esculin, galactose, glycerol, glycogen, inulin, lactose, mannitol, mannose, melezitose, raffinose, rhamnose, salicin, sorbitol, or sorbose. Nitrate reduction is positive for some strains. Esculin and gelatin are not hydrolyzed; indole, and acetoin are not produced. Hemolysis-negative. Weak production of gas and weak growth in 20% bile.

Cell walls contain alanine, glutamic acid, lysine, and aspartic acid. Glucose, galactose, and mannose are the principal cell-wall sugars. Major fatty acids are $C_{18:1}$ ω9*c*, $C_{15:0}$ anteiso, and $C_{16:0}$; smaller amounts (>2 < 5%) of $C_{14:0}$, $C_{15:0}$ iso, $C_{17:0}$ anteiso, and $C_{18:1}$ ω7*c* are present.

Source: urinary tract infections and a mesenteric ganglion of a monkey. Strains originally described by Torrey (1916) were from lymph nodes of patients suffering from Hodgkin's disease.

DNA G+C content (mol%): 53–54 mol% (T_m), 56 (HPLC).

Type strain: ATCC 27520, CCUG 27816, CIP 103263, DSM 4903, JCM 5829, LMG 16728, NCTC 11866, VPI 7625B.

Sequence accession no. (16S rRNA gene): AJ003056.

Genus XIII. **Tessaracoccus** Maszenan, Seviour, Patel, Schumann and Rees 1999b, 466^{VP}

Robert J. Seviour and Abdul M. Maszenan

Tes.sa.ra.coc′cus. Gr. adj. num. *tessares* four; N.L. masc. n. *coccus* (from Gr. masc. n. *kokkos* grain, seed) coccus; N.L. masc. n. *Tessaracoccus*, four round cells.

Gram-stain-positive, nonsporeforming, facultatively anaerobic nonmotile cocci 0.5–1.1 μm in diameter, arranged in regular tetrads. **Contains polyphosphate granules**. **Oxidase-negative, catalase-positive, and nitrate reduced**. Cell wall contains LL-diaminopimelic acid with an **A3γ′ peptidoglycan type and a glycine residue at position 1 of the tetrapeptide**. **Major menaquinones are MK-9(H_4) and MK-7(H_4), while the polar lipids are phosphatidylinositol, phosphatidylglycerol, and diphosphatidylglycerol,**

together with three unidentified glycolipids. The major fatty acid is anteiso hexadecanoic acid. Growth at 20–37°C, with the optimal temperature at 25°C. Growth at pH 6.0–9.0 with optimum pH at 7.5.

DNA G+C content (mol%): 74.

Type species: **Tessaracoccus bendigoensis** Maszenan, Seviour, Patel, Schumann and Rees 1999b, 466[VP].

Further descriptive information

Tessaracoccus is currently placed as a member of the family *Propionibacteriaceae* emend. Rainey, Ward-Rainey and Stackebrandt despite different signature nucleotides in some positions (e.g. G–T instead of A–T and A instead of G at positions 602:636 and 686, respectively) from those proposed by Stackebrandt et al. (1997) to circumscribe members of this family (Maszenan et al., 1999b). Only one species, *Tessaracoccus bendigoensis*, is currently recognized. It is related to members of the genus *Propionibacterium* with *Propionibacterium cyclohexanicum*, *Propionibacterium freudenreichii*, *Propionimicrobium lymphophilum*, and *Propionibacterium propionicum* as its closest relatives (Figure 246). It can utilize a wide range of sugars and sugar derivatives, as well as organic acids, although it does not utilize most amino acids and amines (Maszenan et al., 1999b). *Tessaracoccus* was isolated from activated sludge and synthesizes polyphosphate under aerobic conditions, thereby raising the possibility that it might play some role in enhanced biological phosphate removal (EBPR). However, there are not any studies which show this organism occurs in high numbers in such systems, and 16S rRNA targeted probes have not been generated for its *in situ* identification. There is not any evidence that the organism can accumulate poly β-hydroxyalkanoates (Maszenan et al., 1999b), a feature generally considered necessary in any putative polyphosphate accumulating organism in such systems (Seviour et al., 2003). It has also been detected in, but not cultured from, a Cr (IV) degrading community by denaturing gradient gel electrophoresis profiling of its 16S rRNA gene fragments (Arias and Tebo, 2003).

Enrichment and isolation procedures

Tessaracoccus bendigoensis was isolated with difficulty by micromanipulation (Skerman, 1968) from activated sludge biomass taken from an anaerobic:aerobic laboratory scale EBPR sequencing batch reactor seeded from a full scale EBPR activated sludge plant (Maszenan et al., 1999b). The only medium successful for its isolation and subsequent growth was the GS medium described by Williams and Unz (1985).

Maintenance procedures

Tessaracoccus bendigoensis was cultivated on GS medium and incubated at 25°C. After purity was confirmed by microscopic examination, cultures were stored successfully on GS medium in 20% glycerol (v/v) at −80°C.

Taxonomic comments

Only a single strain of a single species of *Tessaracoccus* has been characterized and described so far, hence it seems likely that the genus description may require emending as more species are isolated and characterized. Based collectively on its G+C mol% composition, 16S rRNA gene sequence, menaquinone and fatty acid composition, and its peptidoglycan type (A3γ′), with LL-diaminopimelic acid (LL-A_2pm), and only a single glycine residue in its interpeptide bridge, and glycine at position 1 in the tetrapeptide, *Tessaracoccus* seems to differ markedly from all other genera in the family *Propionibacteriaceae* (Table 213). *Propionimicrobium lymphophilum*, for example, has aspartate as the interpeptide bridge and an A4α cell-wall type (Stackebrandt et al., 2002). In addition to the MK-9(H_4) common to all members of the family *Propionibacteriaceae*, it contains MK-7(H_4), while its predominant fatty acid is $C_{15:0}$ anteiso.

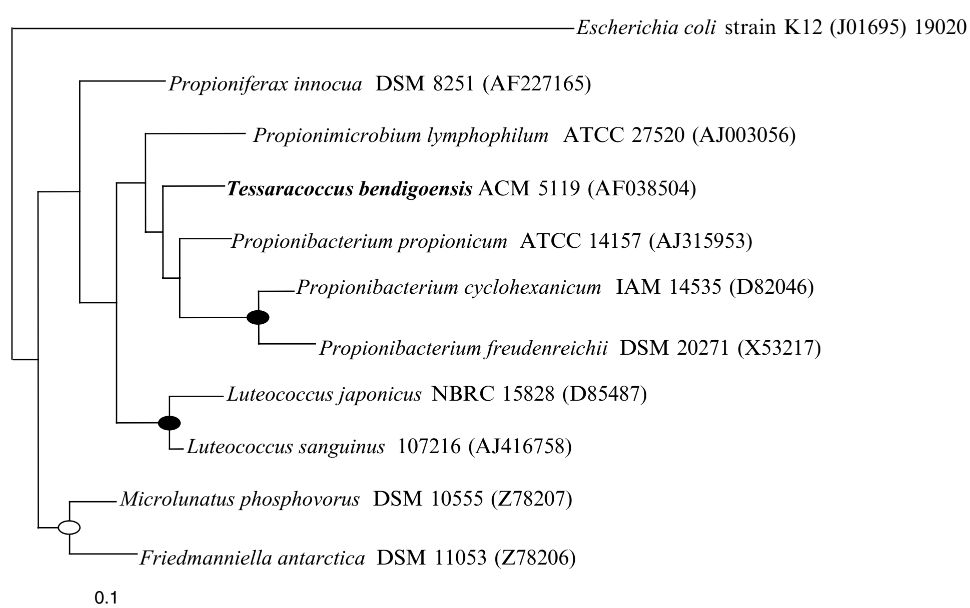

FIGURE 246. Phylogenetic tree based on 16S rRNA sequence data indicating the placement of *Tessaracoccus bendigoensis* within the family *Propionibacteriaceae*. Nodes receiving ≥75% and <97% bootstrap support (1000 replicates) with parsimony and neighbor-joining algorithms (○). Those receiving ≥97% are indicated (●). Scale bar = 0.1 nucleotide substitutions per site.

TABLE 213. Characteristics differentiating *Tessaracoccus bendigoensis* and related taxa[a]

Characteristics	*Tessaracoccus bendigoniensis*	*Luteococcus japonicus*	*Propionibacterium freudenreichii*	*Propionibacterium propionicum*	*Propioniferax innocua*	*Propionimicrobium lymphophilum*
Origin	Activated sludge	Soil and water	Cheese and dairy produce	Human oral cavity and cervicovaginal secretion	Human skin	Lymph nodes of patients
Cell shape and arrangement	Coccoid cells in tetrads	Coccoid cells; arranged in pairs and tetrads	Pleomorphic rods	Pleomorphic rods	Pleomorphic rods	Pleomorphic rods
Optimal temperature for growth	25	26–28	30–32	35–37	37	36–37
Optimal pH for growth (optimum)	6.0–9.0 (7.5)	nd	4.5–8.5	nd	7.0	nd

List of species of the genus *Tessaracoccus*

1. **Tessaracoccus bendigoensis** Maszenan, Seviour, Patel, Schumann and Rees 1999b, 466[VP]

ben.di.go′en.sis. N.L. masc. adj. *bendigoensis* of or belonging to Bendigo, Australia, the place of origin of the isolate.

The following enzymes are detected by APIzyme: *N*-acetyl-β-glucosaminidase, acid phosphatase, alkaline phosphatase, cystine arylamidase, esterase, esterase lipase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, gelatinase, leucine aryl amidase, lipase, α-mannosidase, naphthol-AS-B1-phosphohydrolase, and valine aryl amidase. Produces acetoin, but not H_2S or indole. It can liquefy gelatin, and grows at 20–37°C and pH 6.0–9.0. Optimal growth is at 25°C and optimal pH is 7.5.

The following substrates are utilized as detected with Biolog™: acetate, *N*-acetylglucosamine, amygdalin, L-arabinose, arbutin, α-cyclodextrin, β-cyclodextrin, dextrin, D-fructose, D-galactose, gentiobiose, D-gluconic acid, α-D-glucose, glucose 1-phosphate, glucose 6-phosphate, glycerol, DL-glycerol phosphate, glycogen, α-hydroxybutyrate, DL-lactate, L-lactate, α-D-lactose, lactulose, maltose, maltotriose, D-mannitol, D-mannose, D-melibiose, methyl-α-D-glucoside, methyl-β-D-glucoside, methyl pyruvate, palatinose, pyruvate, D-raffinose, D-ribose, salicin, stachyose, sucrose, turanose, D-xylose, uridine, and UMP.

Source: activated sludge.

DNA G+C content (mol%): 74 (T_m).

Type strain: Ben 106, ACM 5119, DSM 12906, JCM 13525.

Sequence accession no. (16S rRNA gene): AF038504.

No.car.di.o.i.da.ce.a.e. N.L. masc. n. *Nocardioides* type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Nocardioidaceae* the *Nocardioides* family.

Young cultures exhibit different morphologies, ranging from extensively branching vegetative hyphae, growing on and penetrating the surface of agar media, **to irregular rods** and **spherical cells. Aerial hyphae are produced** by organisms of many taxa and may be abundant or scant, at times discernible only microscopically**. The vegetative and aerial hyphae**, depending on organisms and growth conditions, **undergo varying degrees of fragmentation and differentiation eventually resulting in rod-like and coccoid cells (arthrospores)** often arranged in chains or small aggregates. **Cell division and hyphal elongation by pronounced budding** are characteristic of some taxa. **Clusters of tightly packed irregularly shaped cells** can be observed. The non-mycelial bacteria of the genus *Aeromicrobium* and the majority of *Nocardioides* species usually exhibit **a rod–coccoid morphogenetic cycle** and **can be motile. Spherical cells during all growth phases** are characteristic mostly of the genus *Marmoricola*. **Gram-stain-positive type of cell wall.** Non-acid-fast. **Colonies are non-pigmented** or of different intensity and shades of **cream, yellow, or orange.** Aerial mycelium, if any, is typically white, but may be cream or light yellow in color.

Chemo-organotrophs, having a respiratory type of metabolism, with a potential for metabolic flexibility. **Grow under aerobic conditions on standard laboratory media**, including chemically defined (synthetic) media. Some organisms are nutritionally fastidious. Some show weak growth in media rich in organics under anaerobic conditions. Mostly catalase-positive. Oxidase activity varies with the species. Utilize a wide range of carbon and nitrogen sources, including unusual organic compounds and toxic environmental pollutants, and possess a wide spectrum of enzymatic activities. **Mostly mesophiles, non-halophiles. Prefer a neutral to mildly alkaline pH.** However, thermophilic, salt-requiring, and alkaliphilic species occur.

The cell-wall peptidoglycan contains LL-diaminopimelic acid and glycine as the diagnostic amino acid **(the peptidoglycan type A3γ)** The muramic acid residue of the peptidoglycan is *N*-acetylated. **Anionic (acidic) polysaccharides are usually present** in the cell wall, which can be either phosphorous-containing or phosphorous-free (**teichoic, teichuronic, teichulosonic acids** or some not yet identified polymers). Menaquinones are the sole respiratory quinines detected; **the predominant component is menaquinone with partially saturated side chain consisting of either 8, 9, or 10 isoprene units – MK-8(H_4), MK-9(H_4), MK-9(H_6), or MK-10(H_4).** Cellular fatty acids are **different combinations of branched-chain saturated (iso-, anteiso-, 10-methyl- and 9-methyl-branched), straight-chain saturated and monounsaturated, and hydroxylated components.** Mycolic acids are absent. Phospholipids of the three types are present: **type I (with no nitrogenous phospholipids), type III (phosphatidylcholine as diagnostic component), and rarely type II (with diagnostic phosphatidylethanolamine).** Occur in various terrestrial and aquatic environments, including polluted sites, and can be found in microbial communities associated with plants, algae, lichens, animals, or humans. No medically relevant strains or species have been described within the family so far.

DNA G+C content (mol%): 65.5–74.8 (T_m, HPLC).

Type genus: **Nocardioides** Prauser 1976, 61[AL].

Further descriptive information

The family *Nocardioidaceae* (Nesterenko et al., 1985a, 1990; Zhi et al., 2009) belongs to the order *Propionibacteriales*, class *Actinobacteria* (Stackebrandt et al., 1997). Genera currently assigned to this family form a 16S rRNA-based phylogenetic group which includes two main clusters (Figure 247). The first one comprises the genera *Nocardioides* (type genus of the family), *Marmoricola* and *Aeromicrobium*. The second cluster includes the genera *Actinopolymorpha*, *Flindersiella**, *Kribbella*, and *Thermasporomyces**. Delineation of genera within the *Nocardioidaceae*, like in many other actinomycete families, is primarily based on 16S rRNA gene sequence phylogenetic clustering and on morphological and chemotaxonomic characteristics of species included (Table 214).

Morphology. Three main morphological groups can be distinguished among organisms of this family: (1) organisms producing rod-shaped cells and typically displaying a rod-to-coccus morphogenetic cycle, (2) organisms with mostly spherical cells during all growth phases, and (3) organisms forming a mycelium during the morphogenetic cycle. The first morphological group consists of the majority of *Nocardioides* species and all members of the genus *Aeromicrobium*. Cells display irregular rods in young cultures and divide by transverse septum formation, often showing V-forms. While growth proceeds, the cells typically become shorter, and a significant proportion of cells can be coccoid in older cultures. The distinct rod–coccoid growth cycle resembling that of *Arthrobacter* (Keddie et al., 1986) is often observed, especially in synchronized cultures on rich agar media. The second morphological group is mostly represented by coccoid organisms of the genus *Marmoricola*. To this group might also be assigned some *Nocardioides* species producing very short rods and cocci, and showing outward morphological resemblance with *Marmoricola*, e.g. *Nocardioides aquaticus* (Lawson et al., 2000a). The third morphological group encompasses organisms (genera *Actinopolymorpha*, *Kribbella*, *Flindersiella*, *Thermasporomyces*, and two *Nocardioides* species, *Nocardioides albus* and *Nocardioides luteus*) with a common feature of forming branched hyphae but varying significantly in developmental events and cell differentiation (Table 214). Both vegetative (substrate) and, if any, aerial hyphae vary in length and branching intensity, depending on the genus or species and the composition and consistency of the growth medium. The substrate hyphae

*After this chapter was accepted for publication, the descriptions of genera *Flindersiella* (Kaewkla and Franco, 2010a) and *Thermasporomyces* (Yabe et al., 2011) were published. The main characteristics of these genera are outlined only in this chapter and mentioned in the chapters "Genus *Actinopolymorpha*" and "Genus *Nocardioides*" (for further details, see the original descriptions).

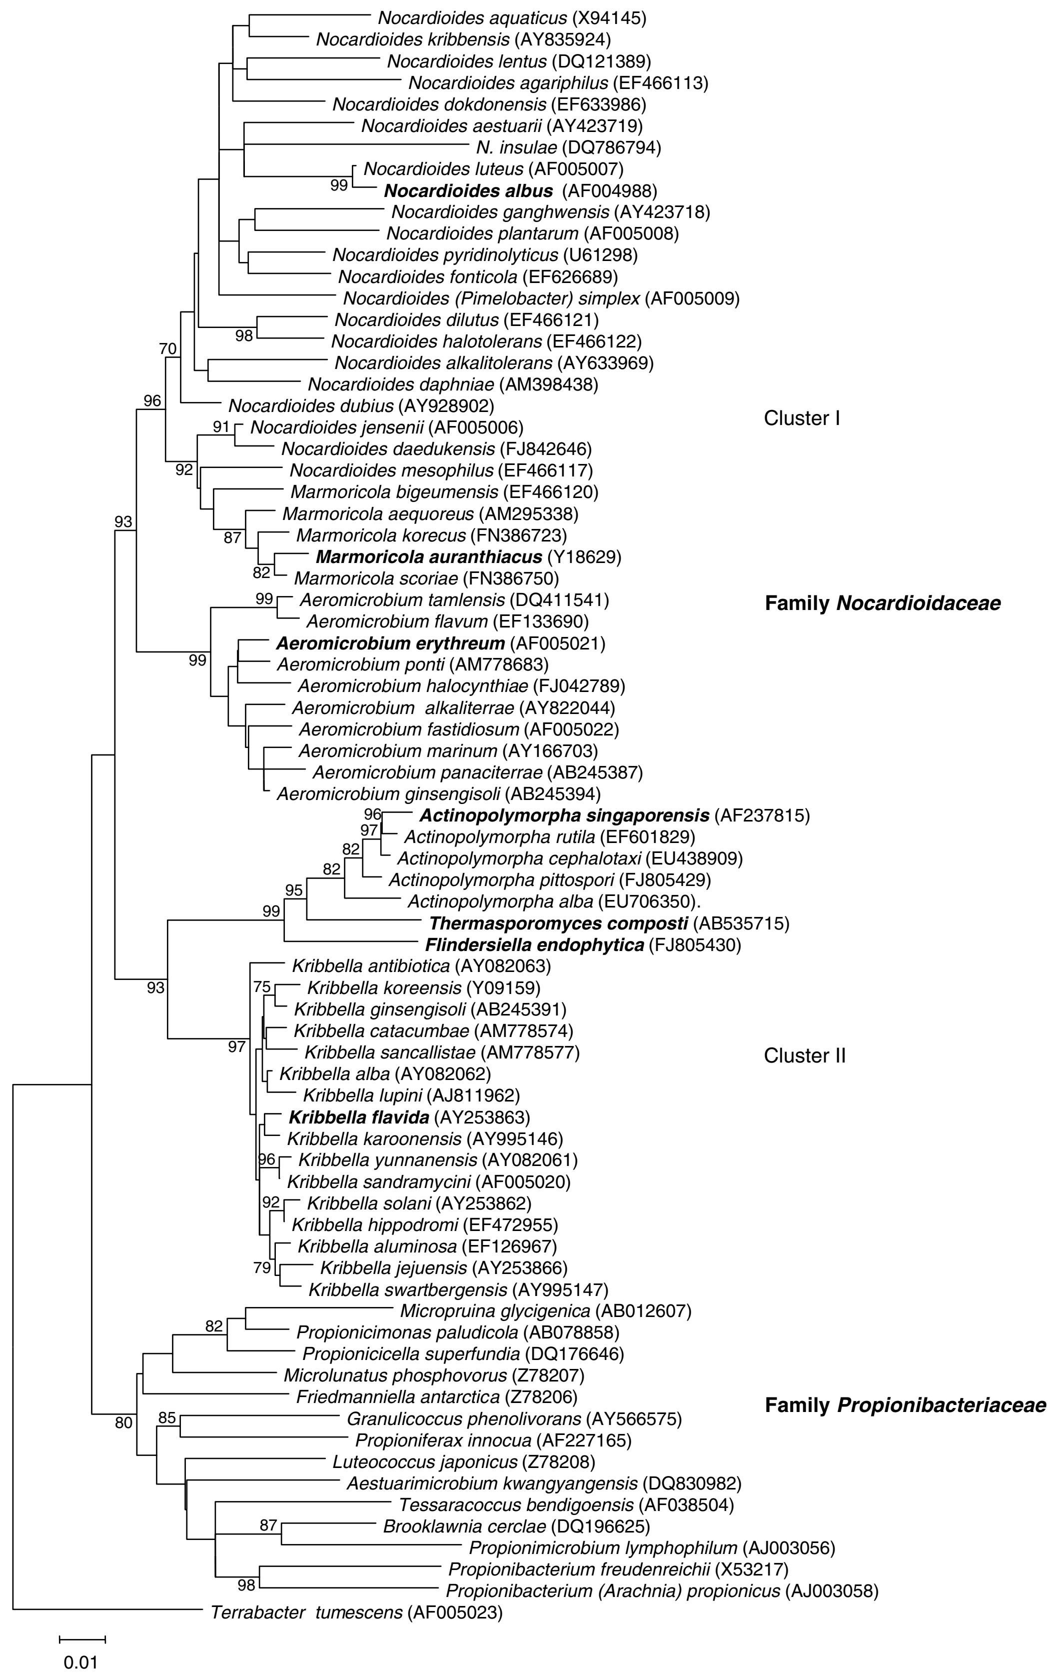

FIGURE 247. Phylogenetic dendogram based on 16S rRNA comparison of type strains of the species comprising the family *Nocardioidaceae* (genera *Aeromicrobium*, *Actinopolymorpha*, *Flindersiella*, *Kribbella*, *Marmoricola*, and *Thermasporomyces*, and representative species of the genus *Nocardioides*). The type species of the genera are given in bold. For the extended tree of the genus *Nocardioides*, see Figure 248. Bar = 0.01 inferred substitutions per nucleotide. Values at nodes indicate bootstrap values for 1000 replicates.

can be of uneven thickness and/or have local swellings, often located at the top of hyphae. The hyphae usually break up into elongated, Y-shaped, or rod-like fragments which can undergo further division by transverse septum formation. The fragments may become thicker and rounder, becoming spore-like cells (arthrospores) after maturation, which can be strung together into short, straight, or zig-zag shaped chains. In some cultures (e.g. in the genus *Kribbella*), the substrate and aerial hyphae or significant hyphal area may remain stable, and no distinct regular fragmentation into rod-like elements can be observed *in situ*. In addition, short chains of poorly to well-differentiated cells (conidia) may occasionally occur on terminal parts of aerial hyphae (*Flindersiella*, *Kribbella*). A characteristic feature of some representatives of the family, especially of the genus *Actinopolymorpha*, is the production of novel cells through marked apical and lateral budding and hyphal elongation by budding (similar to that in *Pseudonocardia*; Henssen, 1989; Henssen et al., 1983), along with the hyphal growth in an ordinary way. Cells produced by budding, and also by septum formation, can form aggregates or compact clusters (most pronounced in *Actinopolymorpha* and some *Kribbella*). The cells in clusters, as recently revealed in kribbellae, are usually tightly packed and irregular in size and shape (often angular) and are produced via transverse and/or differently directed septa, like that reported, e.g. for *Geodermatophilus* (Eppard et al., 1996; Ishiguro and Wolfe, 1970). Both the hyphal fragments and products of other modes of cell fission usually give rise to new hyphae (or buds) when transferred to a fresh medium. Notably, all organisms of the first and the second morphological groups with rod-shaped and coccoid cells fall into the phylogenetic cluster I (Figure 247). The third morphological group, except two nocardioform *Nocardioides* species (*Nocardioides albus* and *Nocardioides luteus*), corresponds to the phylogenetic cluster II.

Chemotaxonomy. All species comprising the genera of the family *Nocardioidaceae* are characterized by the cell-wall peptidoglycan containing LL-diaminopimelic (LL-A_2pm) acid (cell-wall chemotype I *sensu* Lechevalier and Lechevalier, 1970). The peptidoglycan type is A3γ *sensu* Schleifer and Kandler (1972) (type A41.1 according to DSMZ Catalog of Strains, 2001), which was determined for several species (Fiedler et al., 1970; Lawson et al., 2000a; Prauser, 1986; Schippers et al., 2005; Schleifer and Kandler, 1972; Schumann et al., 1997; Trujillo et al., 2006; Urzì et al., 2000) or inferred from available data on the peptidoglycan amino acid composition (e.g. Lee et al., 2000; Miller et al., 1991; Park et al., 1999; Tamura and Yokota, 1994). The subunit of this polymer is characterized by the tetrapeptide L-Ala–D-Glu–LL-A_2pm–D-Ala and a glycine residue as an interpeptide bridge linking the amino group located on the D-carbon of LL-A_2pm and the C-terminal D-alanine of an adjacent subunit. It should be emphasized that this polymer structure differs from those reported for some other LL-A_2pm-containing actinobacteria, belonging, e.g. to the phylogenetically neighboring family *Propionibacteriaceae* or to more distant *Intrasporangiaceae*. Peptidoglycans of organisms of these families may have additional glycine molecules in the interpeptide bridge, along with glycine or glycine amide linked to the α-carboxyl group of D-glutamic acid at position 2 of the peptide subunit (type A3γ; A41.2) or contain glycine instead of alanine in position 1 of the peptide subunit (type A3γ′; A42.1) (DSMZ, 2001; Schleifer and Kandler, 1972; Schumann et al., 1997, 2009; Stackebrandt and Schaal, 2006; Stackebrandt and Schumann, 2006; Weon et al., 2007). Thus, the peptidoglycans of members of the family *Nocardioidaceae* analyzed so far contain one glycine in the peptide subunit, in contrast to that of some *Propionibacteriaceae* or *Intrasporangiaceae*, which may contain up to 4 glycine molecules per peptide subunit. An exception might be the genus *Thermasporomyces* reported to possess peptidoglycan with glycine, glutamic acid, alanine, and LL-A_2pm in a molar ratio of 3.9:1.0:0.6:0.5, although the peptidoglycan structure was not yet studied (Yabe et al., 2011). For a few organisms of the family *Nocardioidaceae*, the acyl type of muramyl residues of the peptidoglycans was determined and found to be acetyl type (Kaewkla and Franco, 2010a; Kubota et al., 2005a; Lee et al., 2000; Uchida and Seino, 1997; Urzì et al., 2000).

The cell-wall monosugars of genera of the family *Nocardioidaceae* routinely recorded during chemotaxonomic studies lack coherence. The sugars revealed in cell walls or whole cells of different species include various combinations of glucose, galactose, mannose, rhamnose, and less frequently 2-*O*-methyl-D-galactose (madurose), 2,3-*O*-dimethyl-D-galactose, ribose, xylose, as well as some unidentified sugars. On the other hand, the neutral cell-wall monosugars may be absent (*Nocardioides plantarum*), while aminosugars, polyols, carbonic acids, and some unusual compounds originating from different types of peptidoglycan-attached polysaccharides may be present (see the chapters on *Aeromicrobium*, *Kribbella*, and *Nocardioides* in this volume for more details). The data available suggest that the monosugar patterns, individual sugars, and/or other components originating from the cell-wall polysaccharides linked to the peptidoglycan are indicative of individual species or species group within a genus and may also predict membership of a bacterium to a certain genus.

The peptidoglycan-linked polysaccharides from representatives of this family were found to possess mostly anionic (acidic) polymers of different types (Table 214). One such acidic polymer type is represented by teichoic acids which are poly(polyol phosphate) polymers often including glycosyl moieties in the basic chain and bearing lateral branches (substituents) (Baddiley, 1970; Ward, 1981). The teichoic acids were found in almost all organisms of the genera *Nocardioides* and *Aeromicrobium* so far analyzed (Naumova et al., 2001; Shashkov et al., 2000b; Shashkov et al., 1999; Takeuchi and Yokota, 1989; Tul'skaya, 2009). The exception is *Nocardioides plantarum* (which lacks teichoic acids and other phosphate-containing polysaccharides, and most likely has a different kind of the peptidoglycan-linked polymer). *Aeromicrobium fastidiosum*, in addition to a ribitol teichoic acid, has another type of phosphate-containing polymer, presumably a phosphorhamnan. Two types of phosphorous-free acidic polymers (along with minor amounts of a neutral glycopolymer, mannan) have been found in the cell walls of 15 *Kribbella* strains representing different phylogenetic groups within the genus (Shashkov et al., 2009; A.S. Shashkov, E.M. Tulskaya, and L.I. Evtushenko, unpublished). One type is represented by teichuronic acids with a rare diaminosugar, 2,3-diacetamido-2,3-dideoxyglucose, in the basic chain. The second type comprises unusual glycopolymers with the backbone containing a nine-carbon sialic-acid-like keto sugar, a nonulosonic (mostly pseudaminic) acid, and is characterized by an unusual linkage in the polymeric chain (Figure 275). By analogy with teichuronic acids, the name for nonulosonic acid-containing polymers was

TABLE 214. Differential characteristics of the genera in the family *Nocardioidaceae*[a]

Symbols and abbreviations: +, present; –, absent; D, different between species within a genus (character for the type species is indicated); anteiso, iso-, 9-Me-, and 10-Me indicate anteiso-, iso-, 9-, and 10-methyl-branched acids, respectively; 2-OH, 2-hydroxylated acids; DPG, diphosphatidylglycerol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PG-OH, phosphatidylglycerol containing 2-hydroxy fatty acids; PGL, ninhydrin-positive phosphoglycolipid; PI, phosphatidylinositol; PI-OH, phosphatidylinositol containing 2-hydroxy fatty acids; PIM, phosphatidylinositol mannosides; PL, unidentified phospholipid(s); GL, glycolipid(s); CAD, cadaverine; PUT, putrescine; SPD spermidine; SPM, spermine.

[a]Data compiled from the original descriptions of the genera, the species composing the genera and publications cited in the respective genus chapters.

[b]Vegetative and aerial hyphae develop in cultures of *Nocardioides albus* and *Nocardioides luteus* only.

[c]Rod-shaped and coccoid cells are usually produced owing to fragmentation of vegetative and/or aerial hyphae, with different genera and species showing varied degrees of hyphal fragmentation and additional cell differentiation.

[d]Coccoid cells are typically produced in later stages of the morphogenetic cycle.

[e]Cells in clusters are often tightly packed and irregular in shape and size (can be produced internally by differently oriented septa, as shown for kribbellae and supposed for *Actinopolymorpha*).

[f]Numerals indicate the numbers of isoprene units and the number of hydrogen atoms in the partially saturated side chain, e.g. 8/4 is a menaquinone with 8 isoprene units and 4 hydrogen atoms in the side chain. Components irregularly detectable among species or reported to occur in lesser amounts are given in parentheses.

[g]Menaquinones 6/4, 7/4, 8/0, 8/2, 8/6, and 9/4 may be produced as minor components or in trace amounts (see the chapter on *Nocardioides* for more details and references).

[h]Menaquinone system including 8/4, 7/4, 8/2, and 6/4 (peak area ratio, 73:4:1:1) has been reported for *Marmoricola aurantiacus* (Urzì et al., 2000).

[i]Menaquinone 9/4 constitutes 93% (Carlsohn et al., 2007) or more of the total.

[j]Numbers before and after colons represent chain lengths and numbers of double bonds of fatty acids; ω indicates the double bond position. Compounds are listed in the order of decreasing amounts and frequency among species within a genus. Compounds found to irregularly contribute more than 10% among species of multi-species genera or in different experiments are given in parenthesis (see the respective genus chapters in this volume for details). Relative amounts of the predominant components in the fatty acid profiles may vary depending on growth conditions and growth phase.

[k]Found only in *Marmoricola bigeumensis*.

[l]PL usually stands for principal unidentified or incompletely identified compounds which may be the same or different. Parenthesis indicates that a compound was present in only some species within a genus. Minor or trace amounts of other unidentified polar lipids may also be present (see respective genus chapters in this volume).

[m]The key components of the phospholipid types II and III (according to Lechevalier et al., 1977) were reported for *Nocardioides daedukensis* and *Nocardioides dubius* (phosphatidylethanolamine) and *Nocardioides furvisabuli* (phosphatidylcholine).

[n]Polyamines found in some representatives of a genus are given in parentheses.

[o]See the text and relevant genus chapters for the composition of polymers indicated. Minor or trace amounts of neutral polysaccharides may occur in organisms of some taxa so far tested.

[p]An exception is *Nocardioides plantarum*, which most likely contains a peptidylglycan-linked polymer of a different type.

[q]Available for the only species, *Aeromicrobium fastidiosum*; this species also contains another polysaccharide, presumably phosphorhamnan.

suggested to be teichulosonic acids (Knirel, 2009). Notably, each *Kribbella* strain contained as the major polysaccharide either teichuronic or teichulosonic acid, or, occasionally both, while a neutral polymer (mannan) was present in varying amounts in all 15 strains investigated. The teichulosonic acids of a different type were found previously (along with some other acidic polymers) in the cell wall of some streptomycetes, including plant pathogenic strains (Shashkov et al., 2002a; Shashkov et al., 2000a; Shashkov et al., 2002b; Tul'skaya et al., 2007; Tul'skaya, 2009). Pseudaminic acid (or its derivatives) are a rather common component of polysaccharides of Gram-negative bacteria (Knirel et al., 2003; Schoenhofen et al., 2006; Vimr et al., 2004); in the cell walls of Gram-positives, the pseudaminic acid and pseudaminic acid-containing polymers have been found so far solely in kribbellae. Lipoteichoic acids (which, in contrast to the cell-wall teichoic acids, are membrane-anchored) were found in abundance in all representatives of the family investigated so far, i.e. in several mycelium-forming *Nocardioides* strains (E.M. Tulskaya and L.I. Evtushenko, unpublished).

Members of the *Nocardioidaceae* are characterized by different types and the predominant components of cellular fatty acids (Table 214). The complex fatty acid type (Suzuki and Komagata, 1983a; Suzuki et al., 1993), which includes both straight- and branched-chain fatty acids (iso-, anteiso, and 10-methyl-branched) and also hydroxylated acids is characteristic of the genus *Nocardioides*. The fatty acid profile of the majority *Nocardioides* species are dominated by $C_{16:0}$ iso which may contribute up to 65–70% (Choi et al., 2007; Kim et al., 2008a; Schumann et al., 1997). Species of the genera *Aeromicrobium* and *Marmoricola*, except *Marmoricola bigeumensis*, contain large proportions of straight-chain fatty acids as well as 10-methyl-branched and hydroxylated acids, whereas iso- and anteiso-branched components are usually present in minor amounts. In contrast, the four remaining (mycelium-forming) genera of the family are characterized by the predominance of iso- and/or anteiso-branched acids (Table 214). The fatty acid profiles in members of the family may vary considerably with culture age, growth conditions and analytical procedure. Nevertheless, the fatty acid type and, in general, the patterns of major fatty acids, together with some rarely encountered components, e.g. 9-methyl branched chain acids (*Kribbella*) appear to be indicative of certain genera (Table 214).

Three phospholipid types *sensu* Lechevalier et al. (1977) can be identified: type I (no nitrogenous phospholipids), type II (phosphatidylethanolamine as diagnostic phospholipid), and type III (phosphatidylcholine as diagnostic phospholipid). Other polar lipids include phosphatidylglycerol, diphosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, hydroxy-phosphatidylglycerol, as well as unidentified phospholipids and glycolipids (Table 214). The type of phospolipids and the pattern of principal polar lipids are uniform in some genera (e.g. *Kribbella*, all species of which contain phosphatidylcholine) and heterogenous particularly in the genera *Nocardioides, Aeromicrobium*, and *Marmoricola*. As with the fatty acids, the polar lipid patterns may be affected by growth conditions and analytical procedure, resulting in conflicting data reported by different authors (see, e.g. Collins et al., 1989, 1983; Komura et al., 1975b; Lechevalier et al., 1981, 1977; Lee and Kim, 2007; O'Donnell et al., 1982; Prauser, 1989; Tamura and Yokota, 1994). Besides, many publications report "unknown" polar lipid components, which might be the same as or different from those identified by other authors. Detailed analysis of the polar lipids in members of the family will indeed increase their discriminative power.

Polyamines have so far been detected in only a few representatives of the genus *Nocardioides* and two strains of *Aeromicrobium* (Busse and Schumann, 1999). In most species, cadaverine (which distinguishes these two genera from the other LL-A_2pm-containing actinobacteria analyzed) was present as the primary polyamine with either putrescine, spermine, or spermidine as a secondary one. Others such as 1,3-diaminopropane, tyramine, and sym-homospermidine were detected in some strains in minor or trace amounts (Busse and Schumann, 1999).

Physiology. Bacteria of the *Nocardioidaceae* are considered to be heterotrophic aerobes growing in media containing peptone and/or yeast extract as well as in chemically defined (synthetic) media with glucose and other sugars or organic acids as sole carbon sources; some require vitamins and other growth factors. Representatives of the family, especially *Nocardioides* strains, also exhibit the capacity to degrade and metabolize recalcitrant molecules, including diverse hydrocarbons and numerous substituted aromatic compounds, many of which are toxic (see respective genera chapters in this volume for references and details). Some species of the genus *Kribbella* show weak or moderate anaerobic growth on agar media rich in organics in an atmosphere of $H_2/CO_2/N_2$ (5:10:85), but not on ISP 9 with glucose as the sole carbon source (Kirby et al., 2006). The ability of some kribbellae to grow aerobically on tap-water agar (Lee et al., 2000; L.M. Baryshnikova and L.I. Evtushenko, recent observations) suggests that they may possess an oligotrophic or even autotrophic lifestyle under certain conditions, as reported earlier for representatives of the genus *Pseudonocardia* (Goodfellow and Lechevalier, 1986; Lechevalier et al., 1986; Mahendra and Alvarez-Cohen, 2005; Parales et al., 1994; Takamiya and Tubaki, 1956). There is some indirect evidence of possible chemolithotrophic growth with CO and hydrogen (King and Weber, 2007; Mattes et al., 2005; Osborne et al., 2010). Bacteria of the family are mostly mesophiles, exhibiting optimal growth within the temperature range 25–37°C; some grow best at 16–26°C (Lawson et al., 2000a). So far, only one thermophilic species, *Thermasporomyces composti*, growing at 35–62°C (optimum growth at 50–55°C) has been reported (Yabe et al., 2011). Some mesophilic species can grow at temperatures up to 45°C (Cao et al., 2009; Kaewkla and Franco, 2010a; Kirby et al., 2006; Song et al., 2011). Members of the family usually prefer a neutral to mildly alkaline pH, but some (representatives of *Marmoricola*, *Kribbella*, and *Nocardioides*) resist alkaline conditions and can grow at initial pH values up to pH 12 (e.g. Dastager et al., 2008b; Lee, 2007a; Lee and Lee, 2010; Lee et al., 2010; Yoon et al., 2005a). Moreover, some species appear to be alkaliphilic, in particular, *Marmoricola scoriae* (optimal growth at initial pH 8–11; Lee et al., 2010). Some species show weak growth at pH 4.5 or slightly below (Everest and Meyers, 2008). Bacteria of the family are largely non-halophiles, but some species of *Actinopolymorpha*, *Aeromicrobium*, and *Nocardioides* require salt, grow best in the presence of NaCl up to 6–8% (w/v), and/or tolerate NaCl concentrations up to 15% (w/v) (e.g. Bruns et al., 2003; Cao et al., 2009; Choi et al., 2007; Kim et al., 2008a; Lawson et al., 2000a; Lee and Lee, 2008; Wang et al., 2001).

Genomic characteristics. The G+C content of the DNA are largely about 70 mol%, varying between 65.5 mol% (HPLC) determined for *Aeromicrobium panaciterrae* (Cui et al., 2007a) and 74.8 mol% (HPLC) reported for *Nocardioides lentus* (Yoon et al., 2006a). The sequences of the internal transcribed spacer (ITS) region of the 16S–23S rRNA gene (Yoon and Park, 2000) and the ribonuclease P (RNase P) RNA gene (Yoon et al., 1998a) were analyzed in representatives of *Nocardioides*, *Aeromicrobium*, and *Kribbella*. It is worth noting that the 16S–23S ITS and RNase P RNA genes do not necessarily show higher sequence differences between genera than between some *Nocardioides* species. In particular, differences were greater between *Nocardioides albus* and some rod-shaped *Nocardioides* species than between representatives of this and the other genera of the family included in the study. The RNase P RNA gene transfer between organisms of this group can probably take place, as follows from the nearly identical (>99% similarity) sequences of this gene in *Nocardioides jensenii* and *Luteococcus japonicus* (*Propionibacteriaceae*) (Yoon and Park, 2000, 2006). The whole genome has been sequenced for only two representatives of the family, a rod-shaped *Nocardioides* sp. JS614 (Copeland et al., 2006; GenBank accession no. NC_008699) capable of assimilating vinyl chloride and ethene as carbon and energy sources (Coleman et al., 2002; Mattes et al., 2005) and the type strain of *Kribbella flavida*, DSM 17836 (Pukall et al., 2010); GenBank accession no. NC_013729). The genome of *Nocardioides* sp. JS614 is represented by a 4.99-Mb circular chromosome, 91% of which possesses a protein-coding capacity (4645 protein coding genes), and harbors 55 predicted pseudogenes. The strain also contains a circular plasmid with DNA G+C content of 68 mol%, which is lower than that calculated for the genome (71 mol%) of this strain. The *Kribbella flavida* genome, a circular chromosome of 7.58 Mb, has 7086 protein-coding genes, 60 RNA genes, 2 rRNA operons, and 143 predicted pseudogenes.

Ecology and habitats. Bacteria of the *Nocardioidaceae* are widespread in soil and also in other terrestrial and aquatic environments, including sub-zero-temperature, deep subsurface, and nutrient-limited ecosystems, as well as sites polluted by toxic organic compounds (for references and details, see respective generic chapters in this volume). They have also been detected in uranium and nuclear waste-contaminated sites (Desantis et al., 2006; Fredrickson et al., 2004). It has been reported that representatives of the *Nocardioidaceae* from desert top soils, along with other bacteria and fungi, survive long-distance transport through the atmosphere by dust storms (Griffin, 2007; Polymenakou et al., 2008) and occur in urban aerosols (Brodie et al., 2007). It is worth mentioning that the dust flux only from the Saharan-Sahel region to the atmosphere approximates 1 billion tons per year (Moulin et al., 1997) and, accordingly, huge bacterial and fungal mass are transferred through the atmosphere. Cells or spores of some *Kribbella* remained alive in a soil sample after exposure at 120°C (dry heating) for 1 h (Kirby et al., 2006). Thus, presumably members of this family, like many other actinobacteria, can survive environmental hazards, including desiccation, low and high temperatures, oxygen radicals, UV damage, toxic compounds, etc.

Bacteria of the family, like other actinomycetes, are considered to be consumers of organic material in ecosystems. Many organisms, especially of the genus *Nocardioides*, show biodegradative activities, secreting a range of extracellular enzymes and exhibiting the capacity to metabolize recalcitrant and toxic environmental pollutants. They may also use traces of organics or engage in chemolithotrophic metabolism with input from some atmospheric gases and minerals. Organisms of the genus *Kribbella*, along with some other soil bacteria, are suggested to utilize hydrogen at low concentrations (in the plant rhizosphere) and might contribute to the function of soil as a sink in the global hydrogen cycle (Osborne et al., 2010). Members of the *Nocardioidaceae* can be associated with plants and may exist as mutualistic plant endophytes (e.g. Collins et al., 1994; Coombs and Franco, 2003; Coombs et al., 2003; Kaewkla and Franco, 2010b, 2010a; Song et al., 2004; Trujillo et al., 2006). They can also occur in association with algae, lichens, fungi, and other eukaryotic organisms, including warm-blooded animals (e.g. Fall et al., 2007; Gill et al., 2006; Harris et al., 2007; Lauer et al., 2007, Lee and Kim, 2007; Li et al., 2007b; Sfanos et al., 2005; Tóth et al., 2008). They have also been found in the human microbiome (Grice et al., 2008, 2009). All members of the family are considered nonpathogenic to humans, vertebrate animals, and plants, although some representatives can be occasionally detected among members of bacterial populations found in diseased humans and plants (e.g. Filion et al., 2004; Harris et al., 2007; Song et al., 2004).

Taxonomic comments

The family *Nocardioidaceae* (Nesterenko et al., 1985a, 1990), as initially described on the basis of data accumulated by that time, included the genus *Nocardioides* (Prauser, 1976) with the species *Nocardioides albus* (Prauser, 1976), *Nocardioides luteus* (Prauser, 1984b, 1985), *Nocardioides simplex* (O'Donnell et al., 1982, 1983), and related organisms containing LL-A_2pm in the cell wall, i.e. *Pimelobacter jensenii* (Suzuki and Komagata, 1983b, 1983c) and *Arthrobacter tumescens* (Conn and Dimmick, 1947; Jensen, 1934). In the same publication, the authors also proposed to reclassify *Pimelobacter jensenii* Suzuki and Komagata (1983b, 1983c) as *Nocardioides jensenii*, but the name was not validated, and treated *Arthrobacter tumescens* (*Pimelobacter tumescens*, according to Suzuki and Komagata, 1983b, 1983c) as a separate taxon outside the genus *Nocardioides*. In this context, the genus *Pimelobacter* with the species *Pimelobacter simplex*, *Pimelobacter jensenii*, and *Pimelobacter tumescens* was validly described by Suzuki and Komagata (1983b, 1983c) almost simultaneously with the proposal of O'Donnell et al. (1982, 1983) to reclassify *Arthrobacter simplex* (Lochhead, 1957) as *Nocardioides simplex*, and shortly before the publication of Nesterenko and colleagues (Nesterenko et al., 1985a) (see the *Nocardioides* chapter, below, for more details on the taxonomic and nomenclatural history of the organisms).

Subsequent taxonomic re-evaluation of this group, involving the use of 16S rRNA analysis, showed that *Nocardioides albus*, *Nocardioides luteus*, *Pimelobacter jensenii*, and *Pimelobacter simplex* formed a common phylogenetic group, whereas *Pimelobacter tumescens* represented a separate line of descent (Collins et al., 1989). Based on the sequence data which were mainly in accordance with the data on polar lipid and fatty acid composition (Collins et al., 1983; O'Donnell et al., 1982), and the results of phage typing (Prauser, 1976), the authors transferred *Pimelobacter jensenii* to the genus *Nocardioides* and reclassified *Pimelobacter tumescens* in a newly established genus *Terrabacter* (currently within the family *Intrasporangiaceae*; Stackebrandt

et al., 1997). Simultaneously, Collins and Stackebrandt (1989a, 1989b) proposed the species *Nocardioides fastidiosus* which was later transferred (Tamura and Yokota, 1994) to the genus *Aeromicrobium* (Miller et al., 1991). In 1994, another species, *Nocardioides plantarum*, was added to the genus *Nocardioides* (Collins et al., 1994). Thus, the four *Nocardioides* species (*Nocardioides albus*, *Nocardioides luteus*, *Nocardioides simplex*, *Nocardioides jensenii*, and *Nocardioides plantarum*) and two species of *Aeromicrobium* (*Aeromicrobium erythromycini* and *Aeromicrobium fastidiosum*) had been recognized by 1997, when E. Stackebrandt and colleagues (1997) proposed the emended description of the family *Nocardioidaceae* in a paper introducing a novel hierarchic classification scheme of actinobacteria, in which delineation of higher taxa was based on the 16S rRNA gene sequence-based phylogenetic clustering and distribution of signature nucleotides.

The remaining genera, i.e. *Actinopolymorpha*, *Flindersiella*, *Kribbella*, *Hongia*, *Marmoricola*, and *Thermasporomyces* were added to this family during the years 1999–2011 as a result of using a taxonomic strategy based on the polyphasic approach (Collwell, 1970; Stackebrandt, 2006; Vandamme et al., 1996) which integrates genomic and phenotypic, including chemotaxonomic, characteristics and assumes a certain level of their consensus while establishing or revising the genera and delineating their boundaries. Among them, the genera *Kribbella* (Park et al., 1999) and *Hongia* (Lee et al., 2000) were independently published by different research teams to accommodate the phenotypically and phylogenetically very similar mycelial organisms. Later, Sohn et al. (2003) reclassified the only species of the genus *Hongia*, *Hongia koreensis*, as *Kribbella koreensis*, providing strong evidence that the name *Hongia* Lee et al. (2000) is a junior heterotypic synonym of *Kribbella* Park et al. (1999).

The genus *Jiangella* was also assigned at its original description to the family *Nocardioidaceae* (Song et al., 2005). The family affiliation of this genus was accepted by Zhi et al. (2009) who suggested an updated structure and 16S rRNA gene sequence-based definition of higher ranks of the class *Actinobacteria*. The authors, along with other proposals concerned with establishment and emendation of higher taxa, provided the emended description of the family *Nocardioidaceae* (comprising the genera *Nocardioides*, *Actinopolymorpha*, *Aeromicrobium*, *Jiangella*, *Kribbella*, and *Marmoricola*). However, the genus *Jiangella* has recently been transferred from the *Nocardioidaceae* to the newly proposed family *Jiangellaceae*, suborder *Jiangellineae* (Tang et al., 2010), which has been elevated to order *Jiangellales* in the present volume. In addition, two novel genera, *Flindersiella* and *Thermasporomyces*, have been added to the *Nocardioidaceae*. All the above data suggest that the current family *Nocardioidaceae* Nesterenko et al. (1990) emend. Zhi et al. (2009) is in need of re-evaluation and further emendation.

Our recent analyses of 16S rRNA gene sequences using different clustering algorithms and different selections of strains, including type strains of *Flindersiella*, *Thermasporomyces*, and representatives of the family *Propionibacteriaceae*, showed, as already mentioned, that the genera comprising the current family *Nocardioidaceae* form at least two separate phylogenetic clusters (Figure 247) which can be equated with families. The two clusters are approximately equidistant from each other and from the cluster of the family *Propionibacteriaceae*; the grouping appears to be consistent with morphological and chemotaxonomic features of the genera encompassed (Table 214). The first group, the *bona fide Nocardioidaceae* (in general, corresponding to the *Nocardioidaceae* Nesterenko et al. (1990) emend. Rainey et. al. (1997), includes the genera *Nocardioides*, *Aeromicrobium*, and *Marmoricola*. The second group, here provisionally named "*Kribellaceae*" comprises the genera *Kribbella*, *Actinopolymorpha*, *Flindersiella*, and *Thermasporomyces*. Properties shared primarily or exclusively by organisms of the bona fide *Nocardioidaceae* include: (a) relatively simple morphology and developmental cycles (mostly irregular rods to coccoid cells, or occasionally fragmenting substrate hyphae giving rise to scant aerial hyphae); (b) the presence of motile cells; (c) significant proportions of straight-chain saturated and unsaturated fatty acids (and their 10-methyl-branched derivatives); (d) one predominating menaquinone (containing a tetra-hydrogenated side chain with 8 or 9 isoprene units) in the respiratory chain; (e) teichoic acids or other phosphorous-containing cell-wall polymers (*Nocardioides*, *Aeromicrobium*).

In contrast to the *bona fide Nocardioidaceae*, the "*Kribellaceae*" comprises organisms which are characterized by: (a) generally more complex cell morphology reflecting more complex developmental events, manifested in the course of their reproductive cycles; (b) the absence of motile cells; (c) fatty acid profile dominated by iso- and anteiso-branched acids with minor quantity of straight-chain components; (d) more complex menaquinone system (and, therefore the respiratory system as a whole) with several major isoprenologues tending to have longer and more saturated side chains; (e) phosphorous-free acidic polysaccharides in the cell wall, i.e. teichulosonic and teichuronic acids (found in *Kribbella*). In addition, representatives of these two groups have different-sized genomes, i.e. 4.99 Mb (*Nocardioides* sp. JS614) and 7.58 Mb (*Kribbella flavida* DSM 17836), with different numbers of protein-coding genes, 4645 and 7086, respectively (Copeland et al., 2006; Pukall et al., 2010). Thus, it appears reasonable to divide the current family *Nocardioidaceae* into at least two families, to reflect more robust phylogenetic grouping of the genera encompassed and to achieve more focused and practicable family definitions. In this way, the bona fide *Nocardioidaceae* would be restricted to the genera *Nocardioides*, *Aeromicrobium*, and *Marmoricola*, while the family provisionally named "*Kribellaceae*" is suggested to include *Kribbella*, *Actinopolymorpha*, *Flindersiella*, and *Thermasporomyces*. Along with the 16S rRNA gene sequence data used to define actinobacterial families, the data on this and the other actinobacterial families tend to suggest the feasibility of the phenotypic circumscription (at least of selected families at the beginning) within the framework of contemporary taxonomic structure of the class *Actinobacteria* and the taxonomic methods presently available.

In general, the current multi-species genera of the group under consideration are clearly defined by 16S rRNA gene sequence clustering (Figure 247), and the allocation of a novel strain to a certain genus is achievable by determination of full or partial 16S rRNA gene sequences. Exceptions are the genera *Marmoricola* and *Nocardioides*, members of which form a common clade at a periphery of the *Nocardioides* radiation. Additionally, *Nocardioides dubius* and some other species rather occupy a phylogenetic position intermediate between this group and the remaining *Nocardioides* species. Correspondingly, phylogenetic delineation of organisms of the genera *Marmoricola* and *Nocardioides* might be problematic owing to this situation and also to uncertainty with the chemotaxonomic differentiation between these two genera (Table 214). Allocation of novel strains to the genus *Marmoricola* or related *Nocardioides* species

can be achieved via the determination of both the phylogenetic position and chemotaxonomic characteristics (mostly fatty acid composition), as well as by comparison with individual species of these two genera.

It is quite likely that the taxonomic structure of the genus *Marmoricola* will be revised to reflect more focused definition of the inter-generic boundaries between *Marmoricola* and *Nocardioides* with removal of *Marmoricola bigeumensis* from the genus *Marmoricola*. Notably, the establishment of the genus *Marmoricola* was based on the priority of differences in morphology, lipid composition, and several secondary-structure-forming nucleotides between the novel strain and the phylogenetically closest *Nocardioides* species (Urzì et al., 2000). The proposal of *Marmoricola bigeumensis*, in contrast, relied mostly on the result of the 16S rRNA gene-clustering (Dastager et al., 2008b), although the organism has a higher (97%) binary 16S rRNA gene sequence similarity to *Nocardioides jensenii* than to the type species *Marmoricola aurantiacus* and markedly differs from the two *Marmoricola* species described by that time (Lee and Kim, 2007; Urzì et al., 2000) at least in fatty acid type (which is commonly considered to be a chemotaxonomic marker differentiating actinobacterial taxa above species level; Kroppenstedt, 1985; Suzuki and Komagata, 1983a). Recent descriptions of two additional *Marmoricola* species (Lee and Lee, 2010; Lee et al., 2010) and a few related *Nocardioides* species provided additional evidence for the *insertae sedis* status of the species *Marmoricola bigeumensis*.

The data accumulated since the original description of the genus *Nocardioides* (Prauser, 1976) tend to suggest that the taxonomic structure of this genus will be re-evaluated to achieve a more coherent phylogenetic and phenotypic circumscription. The original description of the genus *Nocardioides* (created for mycelium-producing actinomycetes with the peptidoglycan type similar to that of the genus *Streptomyces*, and showing susceptibility to specific actinophages) does not reflect characteristics of organisms subsequently described under the generic name *Nocardioides*. At present the genus comprises phylogenetically distant and phenotypically dissimilar species, including both the mycelium-forming and rod-shaped organisms. The most unrelated species show 16S rRNA gene sequence similarity of ~92–93%, which is equal to or lower than cut-off values separating many well-defined genera in this and other actinomycete families. In addition, the differences between some *Nocardioides* species in the 16S–23S ITS and RNase P gene sequences exceed those found between representatives of different genera (Yoon et al., 1998a; Yoon and Park, 2000). As for chemotaxonomic heterogeneity, some *Nocardioides* species differ from the type species in the phospholipid types (*sensu* Lechevalier et al., 1977) which is usually believed to differentiate genera (Kämpfer, 2006; Kroppenstedt and Evtushenko, 2006; Lechevalier et al., 1977, 1981), and in the polar lipid patterns as a whole (Table 214). Strains of several *Nocardioides* species so far tested differ in the second major polyamine (Busse and Schumann, 1999) and in the nature of the peptidoglycan-bound cell-wall polysaccharides (Shashkov et al., 1999, 2000b; Tul'skaya, 2009), although the taxonomic value of such characteristics in the family *Nocardioidaceae* is in need of further evaluation. On the other hand, the cell-wall peptidoglycan structures, which are well recognized taxonomic markers differentiating actinomycete genera, have not yet been determined for the majority of *Nocardioides* species, and might turn out to be dissimilar in some organisms.

It can be expected that further comprehensive study of phenotypic and genotypic characteristics of organisms currently encompassed by the genus *Nocardioides*, including new relevant isolates, and involving the genomic and proteomic data for focused circumscription, will provide stronger grounds for dividing the current genus *Nocardioides* into several genera. Dissection of the taxonomic structure of this genus is consistent with the recent way that classification schemes have been improved for other phylogenetically heterogeneous actinomycete genera. Phenotypic (chemotaxonomic) characteristics in particular were used to discriminate between incoherent species and establish separate genera (Behrendt et al., 2011; Tamura et al., 2009, and other studies published in IJSEM during the last decade). Dissection is also in line with the recent tendencies to describe species with more homogenous sets of strains and very high 16S rRNA gene sequence similarity (99% and higher) to recognized species. The tendencies, in turn, reflect genome variation among strains within current bacterial species evolving in different ecological settings (Konstantinidis et al., 2006; Konstantinidis and Tiedje, 2005, 2007).

Genus I. **Nocardioides** Prauser 1976, 61[AL]

Lyudmila I. Evtushenko, Valentina I. Krausova and Jung-Hoon Yoon

No.car.di.o.i′des. N.L. fem. n. *Nocardia* name of a genus; L. suff. *-oides* (from Gr. suff. *-eides* from Gr. n. *eidos*, that which is seen, form, shape, figure) ressembling, similar; N.L. masc. n. *Nocardioides Nocardia*-like, referring to the similarity of life cycles of the type species of this genus and *Nocardia*.

Abundantly branched vegetative hyphae or irregular rods may be formed in young cultures. The morphogenetic cycle is usually observable, with **different organisms showing more or less complex succession of morphological stages**. The morphogenetic cycle usually starts with the coccoid cells or short rods which may simply germinate into rods or longer filaments, show elementary branching or form extensively branched hyphae on and below the surface of agar media, and may give rise to **aerial mycelium**. The latter consists of irregular, sparsely branching or unbranched hyphae and may totally or partially cover the primary mycelium, or be discernible only microscopically. Both the **vegetative and aerial hyphae and the rod-shaped cells undergo various degrees of fragmentation** (division via septa formation). Fragmentation finally results

in the next generation of short rod-like and coccoid cells. No endospores are formed. **Rod-shaped bacteria may be motile. Gram-stain-positive** type of cell wall. Non-acid-fast. The colony color is mainly **whitish, creamy, or yellow** of different tint and intensity and rarely **orange**. Diffusible pigments are not usually produced. Colonies not covered by aerial mycelium are **mostly pasty**, with **smooth to wrinkled surface**. Chemo-organotrophic, with an oxidative type of metabolism. Predominantly catalase-positive. The level of oxidase activity varies among species. Grows under aerobic conditions on standard laboratory media, including chemically defined (synthetic) media or media with low nutrient concentrations. Certain vitamins or other growth factors may be required. Utilizes a wide range of carbon and nitrogen sources, including unusual organic compounds and toxic environmental pollutants. Mostly mesophilic and neutrophilic; some grow at initial pH values of 5–5.5 and/or 11–12. Mostly non-halophilic, but salt-requiring organisms occasionally occur.

The cell-wall peptidoglycan type is A3γ, with LL-diaminopimelic acid and glycine as the diagnostic amino acids. **Muramic acid is of the acetyl type**. The **cell-wall teichoic acids are present** in most organisms examined. **Menaquinones** are the sole respiratory quinones, the predominant component is **MK-8(H_4)** containing a tetra-hydrogenated side chain with eight isoprene units. **Cellular fatty acids are complex mixtures** of saturated and monounsaturated, straight-chain and iso-, anteiso- and 10-methyl-branched components, including 10-methyl octadecanoic acid (tuberculostearic acid, TBSA), among which **14-methyl pentadecanoic acid ($C_{16:0}$ iso) usually predominates.** Mycolic acids are not present. **The principal phospholipids are typically composed of non-nitrogenous components**, but phosphatidylethanolamine and phosphatidylcholine may occasionally occur. The polyamine patterns usually include **cadaverine as the predominant component**, with putrescine, spermine, or spermidine representing the second major polyamine.

Natural habitats include various terrestrial and aquatic environments. Can be associated with plants, animals, and humans. Some are occasionally found among bacteria associated with human diseases, but considered to be of no relevance to the disease agents.

DNA G+C content (mol%): 67.5 (T_m)–74.8 (HPLC).

Type species: **Nocardioides albus** Prauser 1976, 61[AL].

Further descriptive information

The genus *Nocardioides* belongs to the family *Nocardioidaceae*, order *Propionibacteriales*. Based on the 16S rRNA gene sequence analysis, the species currently comprising this genus form a phylogenetic radiation which is clearly separated from the other genera of the family *Nocardioidaceae*, except for *Marmoricola* (Figure 247 and Figure 248). Several *Nocardioides* species rather occupy intermediate phylogenetic position between the majority of *Nocardioides* species and the genus *Marmoricola* or are intermixed with members of the genus *Marmoricola*. The 16S rRNA gene sequence similarity levels between *Nocardioides* species are quite dissimilar and range from ~92–93 to 99.6%.

Morphology and colony appearance. Bacteria of the genus *Nocardioides* usually display life cycles that most closely resemble those of *Nocardia* or *Arthrobacter*. Information on the mycelium-forming organisms presented in this section is based to a large extent on the works of H. Prauser (Prauser, 1976; Prauser, 1984a; Prauser, 1989).

Visible growth of *Nocardioides albus* and *Nocardioides luteus* and related mycelium-forming organisms is observed within 1–2 d on standard nutrient media. On media rich in organic nitrogen, and in submerged shaken culture, the extent of mycelium development and its persistence are reduced. The hyphae of the primary mycelium are 0.5–0.8 μm in diameter and irregularly septate. Preceding fragmentation, additional septa are formed. Fragmentation of the vegetative hyphae begins in the older parts of the colonies (Figure 249). Depending on the growth media, the elements resulting from fragmentation may be irregular, rod-like, or coccoid (Figure 249 and Figure 250; Prauser, 1989; Suzuki and Komagata, 1983c). The fragments may give rise to new mycelia by extruding one, two, or more hyphae. The irregularly shaped and branched hyphae of the aerial mycelium (Figure 251 and Figure 252) are slightly thicker (0.6–1.0 μm). The aerial hyphae become septate and break up more regularly than those of the primary mycelium. They usually fragment completely into rod- or coccus-like elements that resemble at maturity the surface-smooth conidia (arthrospores) of some streptomycetes (Figure 253 and Figure 254). The spore-like elements germinate by producing one or two germ tubes when transferred to a fresh medium. Motility does not occur at any stage of the life cycle of *Nocardioides albus* and *Nocardioides luteus*. Indeed, the spore-like elements may be unrecognizable *in situ* but observable after mechanical disruption of the mycelium threads. Notably strains may occasionally lose the ability to form aerial mycelium on continued subculture. Both hyphae and fragments show the ultrastructure typical for Gram-stain-positive bacteria (Figure 250 and Figure 254).

The colony appearance of *Nocardioides albus*, *Nocardioides luteus*, and related filamentous organisms is influenced to a large extent by the culture conditions. The colony surface on agar media may be smooth, rough or wrinkled, or covered by aerial mycelium. Depending on the growth medium, individual strain, and the culture age, the aerial mycelium may totally cover the primary mycelium, may be formed only in patches or at the margins of the colonies, may be visible only microscopically or absent. Colonies not covered by aerial mycelium may be dull to bright, but usually are faintly glistening. The colony consistency (mass of the primary mycelium) is mostly pasty, particularly in the center of colonies where hyphal fragmentation begins and in older agar cultures on rich media.

The majority of species currently attributed to the genus *Nocardioides* produce neither primary nor aerial mycelium. Cells of such species are mostly slender irregular rods in young cultures (Table 215; Figure 255, Figure 256, Figure 257, Figure 258, Figure 259A, Figure 261, and Figure 262) that may occur singly, in short chains, in palisades or other side-by-side formations (Figure 258) probably due to adhesive properties. V-forms may be produced. Older cultures of the majority of species predominantly or exclusively consist of coco-bacillary or coccoid cells (Figure 259B). A marked rod-to-coccus morphogenetic cycle resembling that of *Arthrobacter* was reported or suggested for nearly all rod-shaped *Nocardioides* species. Larger club-shaped or spherical forms significantly exceeding the remaining cells in diameter (Figure 257) may be occasionally observable both in young and older cultures (Dastager et al., 2009d; Dastager et al., 2008f, c, 2009e; Jensen, 1934). The cell division proceeds by means of irregular or binary

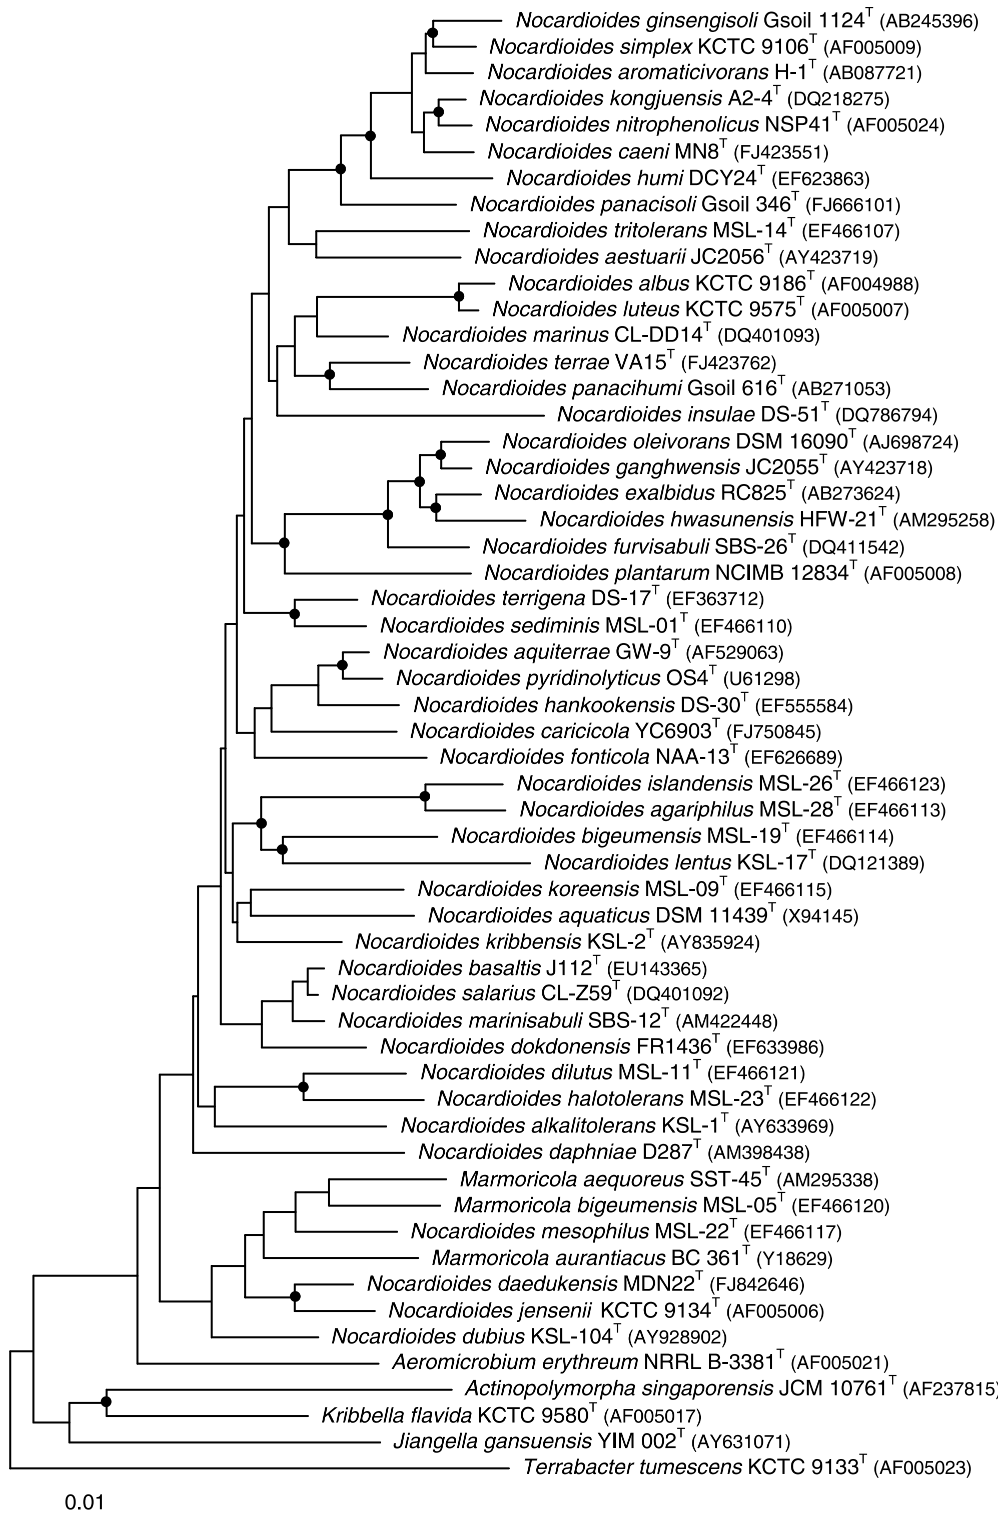

FIGURE 248. Neighbor-joining phylogenetic tree based on 16S rRNA gene sequences showing the positions of *Nocardioides* species and some related taxa. Filled circles indicate that the corresponding nodes were also recovered in the trees generated with the maximum-likelihood and maximum-parsimony algorithms. The bar = 0.01 substitutions per nucleotide position.

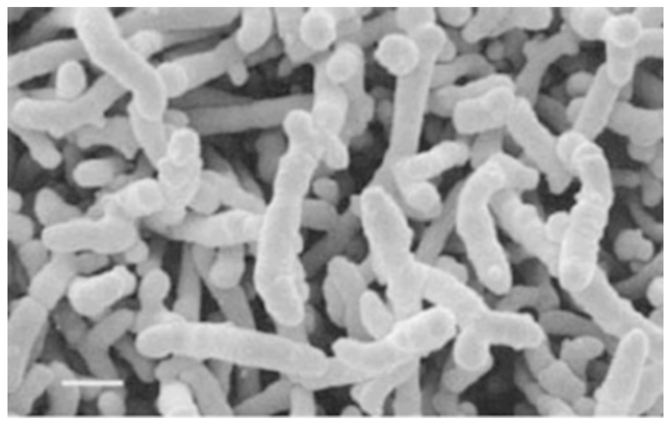

FIGURE 252. Aerial mycelium of *Nocardioides albus* KCTC 9186 on glucose-asparagine agar. Scanning electron micrograph. Bar = 1 µm. (Reprinted from Yoon and Park, 2006. *The Prokaryotes*, 3rd edn, vol. 3, Springer, New York, pp. 1099–1113.)

fission via septa production, so as very short rods or coccoid cells are eventually formed. At the same time, a bud-like mode of cell division may occur. The cell reproduction through constricting was also reported (Kvasnikov et al., 1974). Interestingly, the rod-shaped strain *Nocardioides* sp. JS614, which is the only member of the genus whose complete genome is sequenced, contains a single *ssg* gene that is most likely functionally related to *ssgB* (hypothesized to be essential for septa formation in actinomycetes) (Traag and van Wezel, 2008). The cells may be nonmotile or motile (Table 215) either with single polar, subpolar, or peritrichous flagella (Figure 260, Figure 261, and Figure 262). Colonies of rod-shaped organisms are usually small, circular, convex, or rarely flat, smooth and glistening, with entire margins. They typically are indistinct in color (whitish, light creamy, or yellowish white), with some organisms producing distinct yellow pigments of different tint and intensity; orange-pigmented colonies may occur on some media (Table 215).

Chemotaxonomy. The cell-wall peptidoglycan contains 2,6-LL-diaminopimelic acid (LL-A_2pm), along with alanine, glutamic acid, and glycine. As available for several species (Lawson et al., 2000a; Prauser, 1976; Schippers et al., 2005; Schleifer and Kandler, 1972), the peptidoglycan type is A3γ type *sensu* Schleifer and Kandler (1972); variation A41.1 (http://www.peptidoglycan-types.info). It contains LL-A_2pm in position 3 and L-alanine in position 1 of the tetrapeptide subunit, with a glycine residue forming the interpeptide bridge (like that in the majority of LL-A_2pm-containing actinomycetes). This polymer differs from the

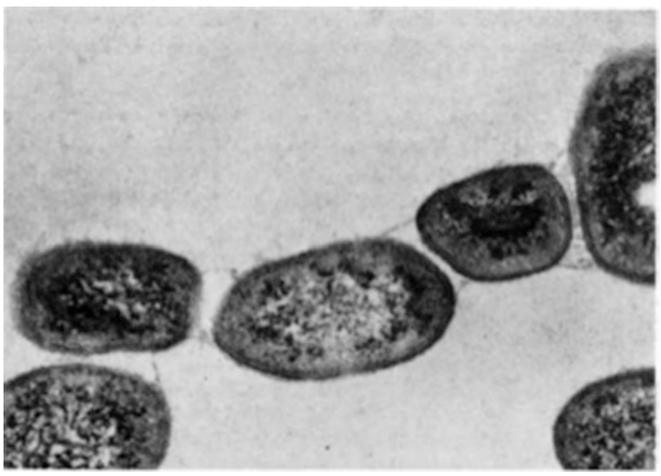

FIGURE 254. *Nocardioides albus*. Developing spore-like elements (arthrospores) still connected by the surface sheath of the aerial hypha. Electron micrograph (~50,000×). (Reprinted from Prauser, 1986. *Bergey's Manual of Systematic Bacteriology*, vol. 2, Williams & Wilkins, Baltimore, pp. 1481–1485.)

LL-A_2pm-based peptidoglycans of some other representatives of the suborder *Propionibacterineae* or the family *Intrasporangiaceae*, which may contain 3 glycine molecules in the interpeptide bridge and glycine or glycine amide at D-glutamic acid of the peptide subunit (type A3γ; variation A41.2), or contain glycine instead of alanine in position 1 of the peptide subunit (type A3γ′; variation A42.1) (Schleifer and Kandler, 1972; Schumann et al., 2009; Stackebrandt and Schaal, 2006; Weon et al., 2007; and the respective chapters in this volume). No isomer of A_2pm was reported for *Nocardioides dilutus*. The acetyl type of the muramyl residues in the cell-wall peptidoglycans was reported for a few *Nocardioides* species so far studied with respect to this characteristic (Kubota et al., 2005a; Uchida and Seino, 1997). The data on cell-wall sugars routinely examined in actinomycetes during taxonomic studies are also available for some species only, namely, *Nocardioides albus*, *Nocardioides luteus*, *Nocardioides simplex*, *Nocardioides jensenii*, and *Nocardioides aquaticus*. These typically include galactose and different combinations of glucose, mannose, and rhamnose (Cummins and Harris, 1959; Keddie and Cure, 1977; Lawson et al., 2000a; Prauser, 1989; Sadikov et al., 1983; Shashkov et al., 2000b; Shashkov et al., 1999; Takeuchi and Yokota, 1989; Tul'skaya, 2009). On the other hand, no monosugars have been revealed in the cell wall of the type strain of *Nocardioides plantarum* (Tul'skaya, 2009).

The cell-wall teichoic acids of different structure were found in strains of *Nocardioides albus*, *Nocardioides luteus*, *Nocardioides jensenii*, *Nocardioides simplex*, and some mycelium-producing organisms of this genus (Evtushenko et al., 1984; Sadikov et al., 1983; Shashkov et al., 2000b; Shashkov et al., 1999; Takeuchi and Yokota, 1989; Tul'skaya, 2009). No phosphorous-containing polymers was revealed in the cell wall of *Nocardioides plantarum* (Tul'skaya, 2009), which, along with the absence of monosugars, is rather indicative of a different kind of the peptidoglycan-linked polymer in this species. The type strain of *Nocardioides albus* possesses a galactosylglycerol phosphate polymer, with repeating units joined by phosphodiester links involving the glycerol C3 and the β-D-galactopyranose C3 atoms. The β-D-galactopyranosyl residues are substituted at C2 with acetate groups and at C4 with β-D-glucopyranose carrying a 4,6 pyruvate ketal group (Shashkov et al., 1999). The type strain of *Nocardioides simplex* was reported to contain a poly(glycerol phosphate) teichoic acid (Sadikov et al., 1983; Takeuchi and Yokota, 1989). Additional sugars (galactose, mannose, glucose, and/or rhamnose) detected by these authors might be involved in the side chains of the polymer(s). The teichoic acid of the type strain of *Nocardioides jensenii* was not identified, but reported to include glycerol, galactose, *N*-acetylglycosamine, and pyruvic acid (Tul'skaya, 2009). Takeuchi and Yokota (1989) revealed galactose and glycerol as predominant components, together with lesser amounts of *N*-acetylglycosamine, glucose, and rhamnose, in a phosphorus-containing polysaccharide fraction of the cell wall of *Nocardioides jensenii*. The type strain of *Nocardioides luteus* and several very closely related strains, including *Nocardioides luteus* ("*Nocardioides flavus*") VKM Ac-2525 (= DSM 46114 = IMET 7844 = J.-S. Ruan, 71-N54) and *Nocardioides* sp. ("*Nocardioides fulvus*") VKM Ac-2526 (= DSM 46115 = IMET 7846 = J.-S. Ruan, 71-N86) have identical 1,5-poly(ribitol phosphate) teichoic acids (Shashkov et al., 1999; Tul'skaya, 2009). All ribitol molecules of these strains are substituted at C4 with α-D-galactopyranosyl residues carrying a 4,6 pyruvate ketal group (Shashkov et al., 2000b; Tul'skaya, 2009). It is noteworthy that regardless of the polymer structure, galactose and pyruvic acid are present in the teichoic acids of all *Nocardioides* strains so far characterized (no precise data are available for *Nocardioides simplex* from early work; Sadikov et al., 1983). High abundance of lipoteichoic acids that, in contrast to the cell-wall teichoic acids, are the membrane-anchored molecules in the cell envelopes, were found in all mycelium-forming *Nocardioides* strains investigated to date (E.M. Tul'skaya and L.I. Evtushenko, unpublished).

The predominant menaquinone in *Nocardioides* species is MK-8(H_4). The data available for some species show that other menaquinones, i.e. MK-6(H_4), MK-7(H_4), MK-8, MK-8(H_2), MK-8(H_6), and MK-9(H_4) may be produced as minor components or in trace amounts (Collins et al., 1994; Collins et al., 1979; Collins et al., 1983; Lawson et al., 2000a; Schippers et al., 2005; Suzuki and Komagata, 1983c; Yamada et al., 1976; Yoon et al., 1997b).

TABLE 215. (continued)

[a]Symbols and abbreviations: +, positive; −, negative; w, weakly positive; v, variable results (between strains, different experiments or the test methods), or conflicting data; nd, not determined. DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PI-OH, phosphatidylinositol apparently containing hydroxylated fatty acids; OH–PG, hydroxy phosphatidylglycerol; PL, unidentified phospholipids; L, unidentified lipids; APG, acylphosphatidylglycerol; PIMs, phosphatidylinositol mannosides. Data are from An et al. (2007), Cho et al. (2010), Choi et al. (2007), Chou et al. (2008), Cui et al. (2009), Collins et al. (1994, 1989, 1979, 1983), Dastager et al. (2009a, 2008d, 2008a, 2008e, 2008f, 2008c, 2009e, 2010), Jones and Collins (1986), Kim et al. (2008a), Kim et al. (2009a, 2009b), Kubota et al. (2005a), Lawson et al. (2000), Lee (2007b), Lee et al. (2007), Lee et al. (2008), Li et al. (2007b), O'Donnell et al. (1982), Park et al. (1999), Park et al. (2008), Prauser (1976, 1984a, 1989), Schippers et al. (2005), Song et al. (2011), Suzuki and Komagata (1983c), Tóth et al. (2008), Yano et al. (1970, 1971), Yi and Chun (2004b, 2004a), Yoon et al. (2008, 2007a, 1999, 2007b, 2009, 2004, 2005a, 2005b, 2005d, 2006a, 2006b, 2010, 1997b), Zhang et al. (2009a) and recent observations.

[b]See also the tree (Figure 248) for phylogenetic position of species and Table 216, Table 217, Table 218, and Table 221 for characteristics of some species groups.

[c]Differences in the color intensity and shade may be influenced by growth conditions and culture age (see also the species description section for more details). For *Nocardioides albus* and *Nocardioides luteus*, the color of vegetative mycelium is indicated.

[d]Cell morphology and size as usually observable in young cultures; some differences in the cell size may be caused by different growth conditions. In older cultures, cells as a rule become shorter and often consist predominantly or exclusively of coccoid or coccobacillary forms (see the species descriptions for details).

[e]The temperature range in which the growth was registered; the actual growth temperature range may be broader for some species (see the species descriptions for further details).

[f]Optimal NaCl concentrations (%, w/v) where available are indicated in parentheses. Zero indicates that addition of NaCl to culture medium is not required for growth, but minor or trace amounts of NaCl may be present. The salinity level may slightly differ depending on the test conditions (see the species descriptions for further details).

[g]Maximal NaCl concentration for growth as registered in the test media used (see the species descriptions for further details); the values may be influenced by the culture medium composition.

[h]Initial pH of test media, with exception of data for *Nocardioides fonticola*; the pH range values may slightly vary depending on the test conditions.

[i]Data on utilization of carbon sources were obtained using different methods, and, therefore, the results presented may not be comparable in some cases. Basal media used in conventional tests to monitor the growth on carbon sources are as follows: *ISP9* (Shirling and Gottlieb, 1966); *B–YC*, basal mineral salts medium (Baumann et al., 1972), supplemented with 2% (v/v) Hutner's mineral base (Cohen-Bazire et al., 1957) and modified by reducing the concentration of sea salts to half-strength (Yi and Chun, 2004a); *LBM*, Leifson's basal medium (Leifson, 1963); *MS1+GF1*, mineral salts medium supplemented with the following growth factors (GF): yeast extract, Oxoid (0.02 g/l), bio-Lactysat, bioMérieux (0.02 g/l), a vitamin solution and a trace element solution (Kämpfer et al., 1990); *MS1+GF2*, the same test medium, but bio-Lactysat is replaced by peptone (Merck) (0.02 g/l) (Kämpfer et al., 1991; Schippers et al., 2005); *MS2+VE*, mineral salts medium supplemented with vitamins and element solution (Cui et al., 2009); *MS3+YE*, mineral salts medium with 0.05 (g/l) of yeast extract (Kim et al., 2008a); *MS4+GF3*, basal test medium containing (per liter) mineral base E (Owens and Keddie, 1969), 0.2 g of Bacto Yeast Extract (Difco), 12 g of agar, 2 µg of vitamin B_{12}, 10 mg of sodium glutamate, and 10 mg of methionine (Collins et al., 1994); *YNB+CA*, Bacto Yeast Nitrogen Base without amino acids (Difco), modified by the addition of 10 mg/l Casamino acids (Difco), and agar (Stevenson, 1967).

[j]Data obtained with the Biolog GP2 test system are displayed in Table 217.

[k]Some differences in quantitative and qualitative composition of phospholipids may be influenced by growth conditions, the culture age and analytical procedure (see the *Further descriptive information* section for more details).

[l]Data from Collins at al. (1983), Lechevalier at al. (1981, 1977), and O'Donnell et al. (1982). Lechevalier et al. (1981, 1977) identified PG, PI, APG, and traces of PIMs (see also the *Further descriptive information* section and Figure 263).

[m]Glycolipids may be detected among principal polar lipids (see the *Further descriptive information* section and Figure 263).

[n]Polar lipids detected in minor amounts are given in square brackets.

[o]*Nocardioides luteus* is generally similar to *Nocardioides albus* in the principal polar lipids (see the *Further descriptive information* section and Figure 263).

[p]DNA base composition as determined by direct quantification of nucleosides by the HPLC method, unless indicated; data for *Nocardioides simplex* were estimated by the thermal denaturation method, with the HPLC-based method for the type strain.

The cellular fatty acid profiles of *Nocardioides* species contain complex mixtures of saturated and monounsaturated, straight-chain and iso-, anteiso- and 10-methyl-branched acids, including 10-methyl-octadecanoic acid (tuberculostearic acid, TBSA), as well as 2-OH and 3-OH hydroxylated acids. In addition, minor quantities of ω-alicyclic fatty acids were reported (Song et al., 2010). The growth (developmental) phase, growth conditions, e.g. temperature, pH, oxygen supply, and growth medium composition (carbon sources, an excessive supply of primer sources) and consistency (solid, liquid), along with analytical procedure, may considerably influence the proportions of principal components or the components considered to be diagnostic for this genus (see Kaneda, 1991; Kroppenstedt, 1985; Suzuki and Komagata, 1983a; Suzuki et al., 1993; Yano et al., 1970, 1971); and also the species descriptions in this chapter). The majority of the data on fatty acids for *Nocardioides* species were obtained using the procedure of Sasser (1990) to extract methyl esters and then gas chromatography analysis. Many recent data were obtained using an automated MIDI system consisting of a Hewlett Packard model 5890 capillary gas chromatograph and a computer with specific software (Microbial ID, Inc., Newark, DE) to automatically identify and quantify the fatty acids.

Comparison of data on fatty acids determined in some *Nocardioides* cultures of different age grown on Nutrient agar (Difco) at 30°C for 4 and 7 d (Yoon et al., 1997a; Yoon et al., 2010) and in some corynebacteria (Suzuki and Komagata, 1983a) demonstrated that the content of TBSA and its homologs increases as the cells aged. On the other hand, the content of 10-methyl acids plus their biosynthetic precursors (respective monoenoic acids) in some analyzed bacteria is rather constant, at least throughout 120 h of cultivation (Suzuki and Komagata, 1983a). Correspondingly, the total contents of these fatty acids

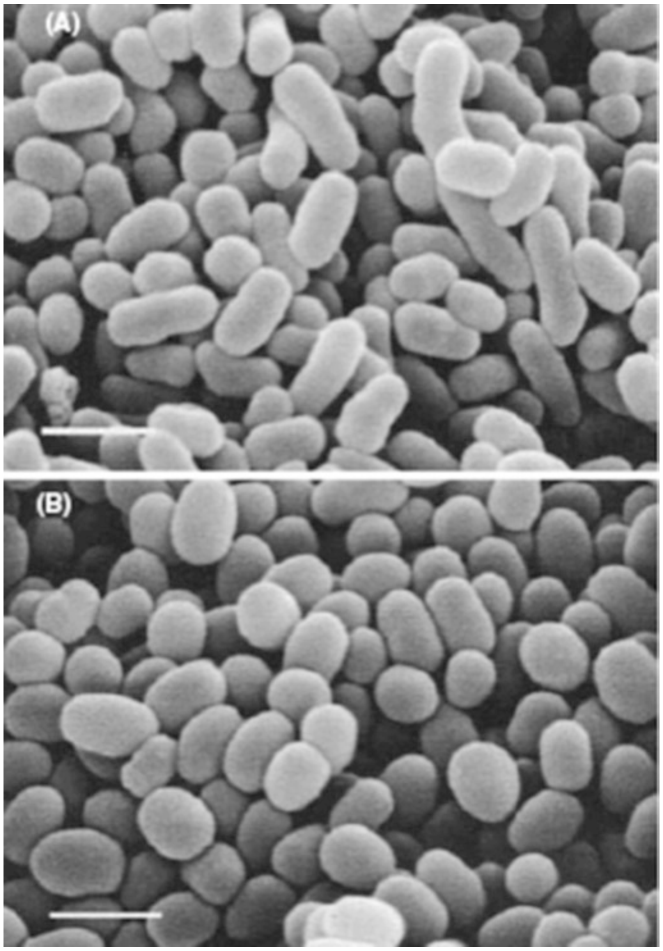

FIGURE 259. *Nocardioides pyridinolyticus* KCTC 0074BP; 3-d-old (A) and 7-d-old (B) cultures on nutrient agar. Scanning electron micrographs. Bar = 1 μm. (Reprinted from Yoon and Park, 2006. *The Prokaryotes*, 3rd edn, vol. 3, Springer, New York, pp. 1099–1113.)

(and other biosynthetically related acids) should be taken into account when comparing the cellular fatty acid compositions of organisms and drawing conclusions about the fatty acid type. In addition, some *Nocardioides* strains grown at higher temperatures usually exhibit a larger proportion of saturated acids (Song et al., 2011; Suzuki and Komagata, 1983a; Yoon et al., 2008). The content of saturated and unsaturated fatty acids may be influenced by the consistency of the medium (liquid, solid) and the extent of aeration. Nevertheless, irrespective of the culture conditions and analytical procedure, the 14-methylpentadecanoic acid ($C_{16:0}$ iso) predominate in most cases and may reach up to 65–82% (Choi et al., 2007; Kim et al., 2008a; Kim et al., 2009a; Schumann et al., 1997; Yoon et al., 2006a). A substantially larger proportion of $C_{16:0}$ iso (65–70%) might be a chemotaxonomic marker of some species, as demonstrated by the data on the phylogenetically closest relatives *Nocardioides salarius* (Kim et al., 2008a) and *Nocardioides basaltis* (Kim et al., 2009b). Similar profiles were obtained independently by different research teams for cultures of different age (1 and 3 d) grown on marine agar (MA; Difco) at 30°C. Very high content of $C_{16:0}$ iso (71.5%) was also reported for *Nocardioides marinus* (MA agar, 30°C, 1 d), also isolated from sea water but phylogenetically distant from the above species (Choi et al., 2007).

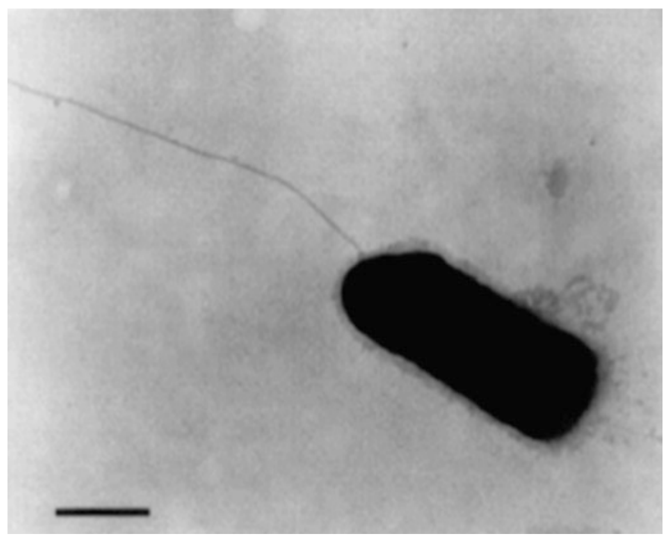

FIGURE 261. Flagellated cell of *Nocardioides nitrophenolicus* KCTC 0457BP; 2-d-old culture grown on nutrient agar at 30°C. Negative stain; transmission electron microscopy. Bar = 0.5 μm. (Reprinted from Yoon et al., 1999. Int. J. Syst. Bacteriol. *49*: 675–680.)

Different predominant fatty acids were also reported, which may be characteristic of certain species or species groups, or reflect the particular culture conditions, or both. For example, a straight-chain unsaturated acid $C_{18:1}$ ω9*c* (27.5%), and $C_{16:0}$ iso (18.6%) were the main components for *Nocardioides oleivorans* (Schippers et al., 2005). In one report (Dastager et al., 2009e), $C_{18:1}$ ω7*c* (50.3%) predominates with a substantially smaller content of $C_{16:0}$ iso (4.2%) for *Nocardioides islandensis* cultured on R2A agar (Difco) for 10 d at 28°C. *Nocardioides aquaticus* grown at 16–20°C also contained an abundance of straight-chain unsaturated acid, $C_{18:1}$ (30.6%), as well as $C_{16:0}$ (14.1%), and $C_{17:0}$ anteiso (10.6%) (Lawson et al., 2000a). *Nocardioides fonticola* had

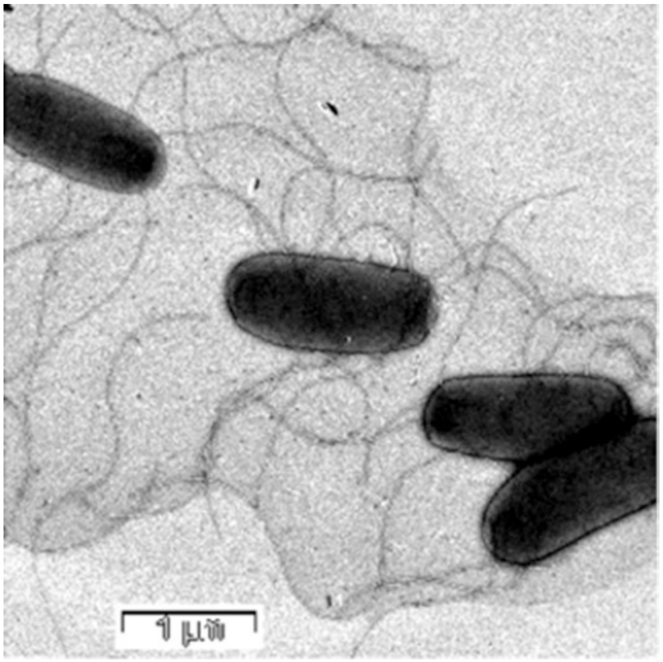

FIGURE 262. Cells of *Nocardioides humi* DCY24 with peritrichous flagella at different developmental stages; cells grown on Luria–Bertani agar at 30°C for 18 h. Transmission electron micrographs of negatively stained cells. Bar = 1 µm. (Reproduced with permission from Kim et al., 2009b. Int. J. Syst. Evol. Microbiol. *59*: 2724–2728.)

$C_{16:0}$ iso and $C_{17:0}$ in equal proportions, nearly 20% when grown on R2A for 3 d at 25°C (Chou et al., 2008). *Nocardioides hankookensis*, on the other hand, contained nearly similar proportions of three acids, $C_{14:0}$, $C_{16:0}$ iso, and $C_{18:1}$ ω5*c* (9–11%) when grown on twofold-diluted R2A agar for 3 d at 30°C (Song et al., 2011), while $C_{16:0}$ iso (42.7%) was found to be the major component in cells mass-harvested from the standard R2A agar after 7 d incubation at 25°C (Yoon et al., 2008). Cells of *Nocardioides furvisabuli*, harvested from MA after incubation at 30°C contained almost equal proportions of $C_{18:0}$ and $C_{16:0}$ iso (19.5%), whereas only $C_{16:0}$ iso (34.1%) was predominating in cells of the same species grown on ISP 2 medium prepared with natural sea water (Lee, 2007b). Strains of *Nocardioides simplex* may exhibit (13–18%) $C_{17:0}$ anteiso larger proportions of $C_{17:0}$ anteiso (13–18%) and $C_{18:1}$ (13–28%) in some experiments (Suzuki and Komagata, 1983c) or have $C_{16:0}$ iso as predominating (reaching up to 41.8%) (Schumann et al., 1997). However, when analyses are performed under identical experimental conditions, strains of this and some other species typically exhibit very similar fatty acid profiles (see, e.g. Lee et al., 2008; Yoon et al., 2005a, 2005b, 2009) and this characteristic may be useful to discriminate *Nocardioides* species, including closely related ones (Cui et al., 2009; Song et al., 2011; Yi and Chun, 2004a; Yoon et al., 1997a, 2010). On the other hand, species (type strains) with rather undistinguishable profiles also occur.

With regard to polar lipids, phosphatidylglycerol (PG), diphosphatidylglycerol (DPG) as well as several incompletely characterized or "unknown" phosphorus-containing or other lipids are typically reported among principal components in *Nocardioides* species (Table 215). The majority of species do not contain nitrogenous phospholipids (i.e. possess phospholipids type I *sensu* Lechevalier et al., 1981, 1977). On rare occasions, nitrogenous phospholipids, such as phosphatidylethanolamine (PE) (Yoon et al., 2005d, 2010) and phosphatidylcholine (PC) (Lee, 2007b) were reported, that are diagnostic of phospholipid types II and III (Lechevalier et al., 1977, 1981). The other phospholipids revealed for some organisms of this genus included phosphatidylinositol (PI), hydroxy-phosphatidylglycerol (PG-OH), acylphosphatidylglycerol (APG), and phosphatidylinositol mannosides (PIMs) (Collins at al., 1983, 1989; Lechevalier et al., 1981, 1977; O'Donnell et al., 1982; see Table 215). It should be emphasized that certain "unknown" phospholipids reported by different authors for some *Nocardioides* species may correspond to those identified (named) in other studies, or only slightly differ from such phospholipids in R_f value owing to some differences in chemical structure of the components involved, mostly fatty acids. Indeed, different patterns of principal phospholipids were reported for some strains in this bacterial group (e.g. Collins et al., 1989, 1983; Komura et al., 1975a; Lechevalier et al., 1977, 1981; O'Donnell et al., 1982; Tamura and Yokota, 1994; Yano et al., 1970, 1971). Glycolipids are usually not mentioned among major polar lipids for *Nocardioides* species. However, several distinct glycolipids can be detected in *Nocardioides albus*, *Nocardioides luteus* (Figure 263), and some other *Nocardioides* strains.

There is now substantial evidence for the effect of culture conditions on the quantitative and qualitative composition of polar lipids in *Nocardioides* strains (which is reminiscent of the phenomenon known for the cellular fatty acids). A prominent example is the polar lipid profile of *Nocardioides albus*. Lechevalier et al. (1981, 1977) reported the presence of PG, PI, APG, and traces of PIMs for *Nocardioides albus*, emphasizing the lack of DPG. According to O'Donnell et al. (1982) and Collins et al. (1983), DPG still occurs among the major phospholipids of this species, along with PG and several incompletely characterized phospholipids, two of which supposedly contain a 2-hydroxy acid. In our recent experiments (N.G. Vinokurova and L.I. Evtushenko, unpublished), both young (8 h, mycelial stage) and older (24 h, fragmentation stage) cultures contained PG, DPG, PL_1 (supposedly APG, run above the DPG spot, just after neutral lipids) and two (or three) characteristic very closely related phospholipids. One of them is most likely PI (contained inositol) and the second was tentatively identified as hydroxy-acid-containing phosphatidylinositol (PI-OH). The older cultures *Nocardioides albus* and *Nocardioides luteus* differed from young cultures mainly in that they contained additional glycolipids (varying amounts) and had an unknown phosphorous-involving yellowish-pigmented compound PL_x in some experiments (Figure 263C, D). The latter, which stained well with Mo-blue (Dittmer and Lester, 1964; Komagata and Suzuki, 1987), shows very weak coloration when sprayed with 5% molybdophosphoric acid in ethanol, but has no distinct specific staining either with ninhydrin, α-naphthol (Jacin and Mishkin, 1965; Komagata and Suzuki, 1987), periodate Schiff reagent (Komagata and Suzuki, 1987; Minnikin et al., 1977) or 5% $AgNO_3$ in aqueous ammonia solution. Certain differences between the polar lipid patterns of *Nocardioides albus* and *Nocardioides luteus* also occur, especially in older cultures (Figure 263C, D). Notably, PL_1 (supposedly APG and/or another closely related compound) characteristic of *Nocardioides albus* and *Nocardioides luteus*, was not revealed in *Nocardioides simplex*. Thus, the polar lipid pattern, even with some components incompletely identified and varying to some extent between experiments, may serve to differentiate species

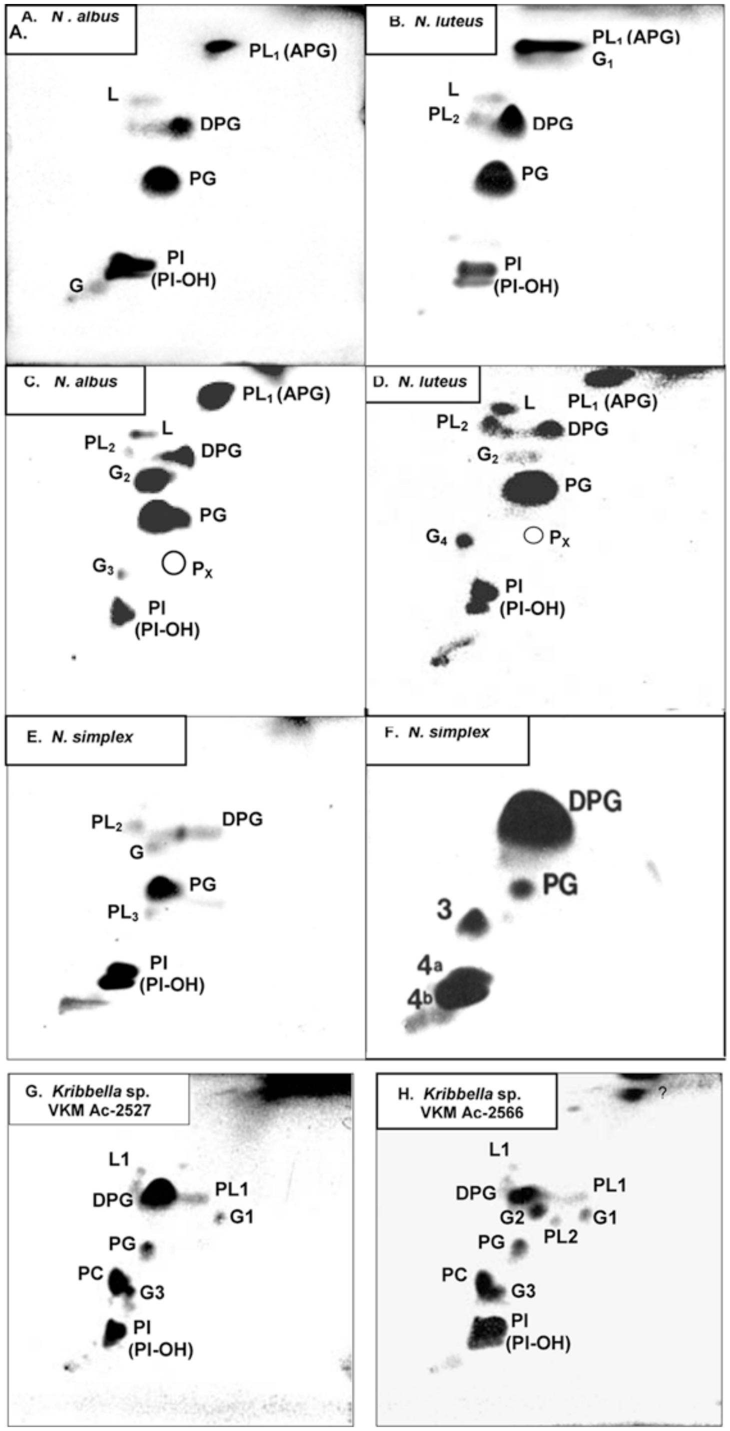

FIGURE 263. Two-dimensional thin-layer chromatograms of polar lipids from the type strains of *Nocardioides albus*, *Nocardioides luteus*, *Nocardioides simplex*, and representatives of the genus *Kribbella* (A–D) Polar lipids of *Nocardioides albus* VKM Ac-805 and *Nocardioides luteus* VKM Ac-1246 in young (nonfragmenting mycelium) (A, C) and older (fragmentation stage) (B, D) cultures grown in complex liquid medium, PYGP (peptone, 0.5%; yeast extract, 0.3%; glucose, 0.5%; K_2HPO_4, 0.02%; pH 7.2). Chloroform-methanol-water (65:25:4, by vol.) was used in the first direction and chloroform-acetic acid-methanol-water (80:15:12:5, v/v) in the second direction (modified from Minnikin et al., 1977). (E and F) Polar lipids patterns from subcultures of the type strain of *Nocardioides simplex*, VKM Ac-1118 (E) and *Nocardioides simplex* NCIB 8929 (F) grown under different conditions. (G and H) Examples of PC-containing polar lipids patterns from nocardioform strains of *Kribbella* (PYGP, 16 h, 28°C; mycelial stage). Abbreviations: DPG, diphosphatidylglycerol; PG, phosphatidylglycerol; PI, phosphatidylinositol; PI-OH, a compound (supposedly phosphatidylinositol) that contains hydroxylated fatty acid(s); PL, unknown phospholipids; PL_1, supposedly acylphosphatidylglycerol (APG); G, glycolipids; L, unknown non-phosphorylated polar lipid; P_x, unknown phosphorus-containing pigment (see the text for details). (A–E, G, and H are courtesy of Natalia G. Vinikurova; F is reprinted from O'Donnell et al., 1982. Arch. Microbiol. *133*: 323–329.)

within this genus and from members of other genera. For differential purposes, the polar lipid patterns have to be analyzed under standardized and controlled experimental conditions and in the same laboratory. Further detailed studies of polar lipids in members of the genus *Nocardioides* will elucidate the spectra of the polar lipid components characteristic of particular species (species groups) and hopefully increase the discriminative power of this characteristic.

Polyamine patterns have been analyzed for 10 strains comprising five *Nocardioides* species (Busse and Schumann, 1999). The majority of strains grown in liquid R medium (Yamada and Komagata, 1972) contained cadaverine in maximum proportion (34–77%). The second major component (nearly 20% or more) for most strains was putrescine (*Nocardioides albus*, *Nocardioides luteus*, and *Nocardioides jensenii*), spermidine (the type strain of *Nocardioides simplex*), or spermine (*Nocardioides simplex* IMET 10283). For *Nocardioides plantarum*, spermine was found to predominate (42%), followed by cadaverine. This strain was also distinguished by a significantly lower concentration of total polyamines. Other compounds, such as 1,3-diaminopropane, tyramine, and sym-homospermidine, were revealed in lesser or trace quantities, with larger proportions (>10%) of 1,3-diaminopropane and tyramine found in a few strains.

In combination with cadaverine, putrescine (in high concentration and proportion in the majority of *Nocardioides* strains) appears to be useful in distinguishing many species of this genus from *Aeromicrobium*. Both *Nocardioides* and *Aeromicrobium* differed from all other analyzed LL-A,pm-containing coryneform and nocardioform bacteria used in the comparative study (families *Propionibacteriaceae*, *Intrasporangiaceae*, and *Sporichthyaceae*) by the presence of cadaverine among major components (Busse and Schumann, 1999; Yoon et al., 2007b). The distinguishing polyamine patterns, along with the overall polyamine concentrations, indicates the potential of polyamines to differentiate individual species or species groups within the genus, as demonstrated by the data on major and additional polyamines for the type strains: *Nocardioides albus* DSM 43109 (cadaverine, 49%; putrescine, 50%); *Nocardioides luteus* DSM 43366 (cadaverine, 57%; putrescine, 28%; spermidine, 11%); *Nocardioides jensenii* DSM 2064I (cadaverine, 54%; putrescine, 22%; spermidine, 12%; spermine, 9.3%); *Nocardioides plantarum* DSM 11054 (spermine, 42%; cadaverine, 34%; tyramine, 12%; 1,3-diaminopropane, 6.8%; spermidine, 5.1%); *Nocardioides simplex* DSM 20130 (cadaverine, 57%; spermidine, 19%; putrescine, 15%; spermine, 5.6%; 1,3-diaminopropane, 4.2%). Notably, the polyamine profiles of strains within the species *Nocardioides albus* and *Nocardioides simplex* (for which more than one strain were studied) were not uniform. A prominent example is the pair *Nocardioides albus* DSM 43874 (53% cadaverine, 30% putrescine, 15% 1,3-diaminopropane, with the total polyamine concentration of 1.5 μmol/g, dry wt) and the type strain *Nocardioides albus* DSM 43109 (49% cadaverine and 50% putrescine, and the total polyamine content of 10.5 μmol/g). The heterogeneity of the polyamine patterns, at least for strains referred to as *Nocardioides albus*, is most likely evidence for the presence of different species within this group (see *Taxonomic comments* for more information). Further studies of polyamines in *Nocardioides* strains strictly proven to be members of one species will elucidate the polyamine set of diagnostic importance for individual species or species groups within the genus.

Nutrition and growth conditions. Strains of *Nocardioides* species usually grow well in standard nutrient media with glucose, peptone, and yeast extract under aerobic conditions. Some organisms of this genus prefer the nutrient-poor media, including a tenfold-diluted nutrient agar (NA; Difco) (Yoon et al., 2005a, 2005b, 2005d), tenfold-diluted R2A agar (Difco) (Dastager et al., 2008f), and some other diluted complex media. Knowledge of minimal nutritional requirements of *Nocardioides* species is incomplete. Most species are nutritionally non-exacting and grow well on a suitable minimal salts medium, e.g. ISP 9 (Shirling and Gottlieb, 1966)* with glucose or other compounds as a sole carbon and energy source and an ammonium salt as a sole nitrogen source (Table 215).

Some organisms, including *Nocardioides albus*, *Nocardioides luteus*, *Nocardioides dokdonensis*, *Nocardioides exalbidus*, *Nocardioides jensenii*, and *Nocardioides simplex* (Collins et al., 1989; Keddie et al., 1986; Li et al., 2007b; Park et al., 2008) and probably many others can use nitrate as a sole nitrogen source. Traces of complex organic substrates (e.g. yeast extract or casein peptone) in minimal salts media commonly enhance growth rates and biomass production of *Nocardioides* species. The good growth of *Nocardioides plantarum* was reported to require thiamine (Collins et al., 1994), while that of *Nocardioides aquaticus* needed both thiamine and biotin (Lawson et al., 2000a). However, both these organisms can grow in the absence of thiamine and biotin (Yi and Chun, 2004a), e.g. in a mineral salts medium consisting of the basal medium (BM; Baumann et al., 1972, 1971) supplemented with 2% (v/v) Hutner's mineral base (Cohen-Bazire et al., 1957), and modified by reducing the concentration of sea salts to half-strength. The BM medium (Baumann et al., 1971) contained 50 mM tris(hydroxymethyl) aminomethane [(Tris)-hydrochloride pH 7.5], 190 mM NH_4C1, 0.33 mM $K_2HPO_4 \cdot H_2O$, 0.1 mM $FeSO_4 \cdot 7H_2O$, and half-strength artificial sea water (MacLeod, 1968).

Some mycelium-forming non-pigmented *Nocardioides* strains (capable of growing on glucose or sucrose with ISP 9 as a basal medium) can utilize other sugars (L-rhamnose, D-xylose, and D-mannitol) as carbon and energy sources only in the presence of thiamine or a vitamin solution (thiamine, riboflavin, nicotinic acid, pyridoxine, and *p*-aminobenzoic acid) (Suzuki and Komagata, 1983c). A similar situation probably takes place with some other species, carbon sources, and growth factors. Some components (or their concentrations) of the above vitamin solution probably inhibit growth or growth rate (Suzuki and Komagata, 1983c). The ability to grow in mineral salts medium with certain carbon sources may also depend on other specific test conditions (e.g. composition of salts in the test medium, carbon source concentrations, the growth medium used to obtain cells for testing, amount of cell mass used as inoculate, etc.).

Bacteria of this genus are largely non-halophilic and neutrophilic mesophiles. A few species, particularly isolated from marine and marine-related environments are salt-requiring and/or grow better in the presence of 0.5–6% NaCl and show resistance to NaCl concentration up to 10–15% (w/v) (Table 215). Some organisms (*Nocardioides bigeumensis* and *Nocardioides caricicola*), in contrast, were reported to be highly sensitive to salt and did not grow even in the presence of 1% (w/v) NaCl (Dastager et al., 2008d; Song et al., 2011). A number of species

*See Shirling and Gottlieb, (1966) (Int. J. Syst. Bacteriol. *16*: 313–340) for the composition of ISP media cited here and in other sections of this chapter.

may start growth at pH 5–5.5 and/or pH 11–12, while others grow in a narrow pH range (pH 7–9) (Table 215). The reported optimal growth temperatures vary insignificantly among species (most organisms grow well between 25 and 30°C; some show best growth at lower temperatures, 16–26°C. Among the recognized *Nocardioides* species, *Nocardioides caricicola* (Song et al., 2011) had the highest growth temperature (45°C) and weak growth was observable for *Nocardioides luteus* (recent experiments). Representatives of several species, i.e. *Nocardioides albus*, *Nocardioides aquiterrae*, *Nocardioides humi*, and *Nocardioides panacisoli* exhibit growth at 42°C (Cho et al., 2010; Kim et al., 2009b; Prauser, 1984b; Yoon, 2004). However, not all organisms have been tested for growth at 42 and/or 45°C.

Metabolism, enzymic and degradative activities. Bacteria of this genus are commonly considered to be chemo-organotrophic aerobes that are able to utilize and degrade a wide range of carbon and energy sources, including various unusual organic compounds. The ability to grow in nutrient-poor media, as well as the finding of representatives of *Nocardioides* in environments of nutrient scarcity, e.g. in cavities (Barton et al., 2004; Groth and Saiz-Jimenez, 1999; Groth et al., 2001), suggests that they may be sufficiently adapted to the oligotrophic lifestyle, be involved in a complex metabolic network of oligotrophic microbial communities, or even engage in chemolithotrophic metabolism with possible input from some atmospheric gases and minerals. In particular, strain *Nocardioides* sp. JS614 is probably able to grow chemolithotrophically on CO, as it might be suggested both from the finding of form I *Cox* genes in its genome (Mattes et al., 2005) and the experiments demonstrating CO-oxidizing activity and chemolithotrophic growth on CO by some actinomycetes containing this gene (King and Weber, 2007). The ability of strains of the recognized species to grow anaerobically on heterotrophic media under different gas atmospheres was not revealed (An et al., 2007; Chou et al., 2008; Cui et al., 2009; Dastager et al., 2008c, 2009e, 2010; Kim et al., 2008a; Lawson et al., 2000a; Schippers et al., 2005; Tóth et al., 2008; Yi and Chun, 2004a, 2004b).

All or the majority of *Nocardioides* strains studied taxonomically possessed activity for esterase lipase (C 8) (conflicting results were reported for a few species by Cho et al., 2010), but were negative in tests for β-glucuronidase, α-fucosidase, and α-mannosidase (API ZYM, bioMérieux). A limited number of strains tested to date (mostly by the API 20NE system; bioMérieux) were negative in the tests for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase. Negative results were also typically registered in the tests for production of H_2S from peptone or cysteine. The only species, *Nocardioides panacisoli*, was reported to produce H_2S from thiosulfate (Cho et al., 2010). For all strains studied so far, tests showed no utilization of thiamine, L-ascorbate, salicylate, 2-propanol, dulcitol, erythritol, sorbitol, xylitol), and polyethylene glycol as carbon sources (Kubota et al., 2005a; Yi and Chun, 2004a, 2004b; Yoon et al., 2009). The results of Voges–Proskauer test vary with species and experiments (Cui et al., 2009; Lee, 2007b; Yoon et al., 2009). The ability to degrade adenine is uncommon (Prauser, 1989; Yi and Chun, 2004a, 2004b), although many species degrade DNA (Table 215) and some utilize thymine (Collins et al., 1994). Although conventional tests have not shown pronounced cellulolytic activity or utilization of cellulose (carboxymethylcellulose) as a sole or principal carbon source in recognized *Nocardioides* species, some unnamed strains of this genus were found to degrade rice straw pieces in minimal salts medium (Abdulla and El-Shatoury, 2007) and many species possess some relevant enzymatic activities. A few organisms can degrade chitin (Prauser, 1976; Tóth et al., 2008) or xylan (Park et al., 2008). Several bacteria were unable to decompose alginate (Lawson et al., 2000a; Yi and Chun, 2004b, a). Varying or conflicting test results (Table 215) for some characteristics of some species (type strains) were reported by different or the same authors. In most cases (disregarding obvious technical mistakes), such data indicate that a particular activity or ability exists, but it is weak or indistinct under the experimental conditions employed.

A prominent feature of members of the genus *Nocardioides* is their capability of performing transformation and degradation of complex and unusual compounds, including very common persistent and toxic environmental pollutants. Examples of such compounds and pollutants include alkanes of various lengths, petroleum chemicals, crude oil and its derivatives (Hamamura and Arp, 2000; Hamamura et al., 2001; Iizuka and Komagata, 1964; Jung et al., 2002; Purswani et al., 2008; Schippers et al., 2005), including carbazole, a recalcitrant *N*-heterocyclic aromatic compound derived from crude oil, creosote, and shale oil (Inoue et al., 2007; Inoue et al., 2006), as well as a sulfur heterocyclic compound dibenzothiophene (Sandhya et al., 1997; Sandhya et al., 1995). There are reports on the ability of members of this genus to degrade and utilize phenols and nitrophenols (Collins et al., 1994; Cui et al., 2009; Gundersen and Jensen, 1956; Keddie et al., 1986; Yoon et al., 2009), including 2,4-dinitrophenol and 2,4,6-trinitrophenol (picric acid) (Behrendt and Heesche-Wagner, 1999; Cho et al., 1998, 2000; Ebert et al., 1999, 2001; Rajan et al., 1996; Yoon et al., 1999), as well as pyridine (Lee et al., 1994; Lee et al., 1991; Rhee et al., 1997; Yoon et al., 1997b). They are capable of degrading a three aromatic ring compound, phenanthrene (Iwabuchi and Harayama, 1997, 1998a, 1998b; Saito et al., 1999, 2000), heterocyclic compounds such as dibenzofurans and chloroaromatics, including dibenzo-*p*-dioxins (Futamata et al., 2004; Inoue et al., 2007; Inoue et al., 2006; Kubota et al., 2005a; Sukda et al., 2009) and 2,4,5-trichlorophenoxyacetic acid which is one of the most persistent herbicides (Ebert et al., 1999, 2001; Golovleva et al., 1990; Männisto et al., 2001; Männisto et al., 1999; Traag and van Wezel, 2008; Travkin et al., 1999). There are reports on the ability to degrade different other herbicides, including *s*-triazine herbicides (Mulbry et al., 2002; Topp et al., 2000; Vibber et al., 2007; Yamazaki et al., 2008). *Nocardioides* sp. PD653 is the first naturally occurring aerobic bacterium reported to be capable of mineralizing hexachlorobenzene, a recalcitrant environmental pollutant, and degrading pentachloronitrobenzene (Takagi et al., 2009).

Nocardioides sp. JS614 is one of the most studied representatives of *Nocardioides* with respect to degradative activities, genetics, and metabolism (Chuang and Mattes, 2007; Mattes et al., 2003, 2005; Owens et al., 2009) and the only *Nocardioides* strain for which the complete genome (CP000509) has been sequenced so far. It is capable of aerobic growth with ethene (a plant hormone and greenhouse gas) and vinyl chloride (a known human carcinogen and common groundwater contaminant), which

is often generated in groundwater by the incomplete reduction of chlorinated solvents (Coleman et al., 2002). This strain also transforms other short-chain alkenes, including propene, 1-butene, and *trans*-2-butene to their corresponding epoxyalkanes, and produces highly enantio-enriched epoxyalkanes via stereoselective monooxygenase-mediated alkene epoxidation (Owens et al., 2009).

Nocardioides simplex and other *Nocardioides* strains possess various enzymes transforming sterols (Arima et al., 1969; Fokina et al., 2003a, 2003b; Nagasawa et al., 1969; Yu et al., 2007). An extracellular adenosine deaminase was described for *Nocardioides* sp. J-326TK (Jun et al., 1994). Histamine dehydrogenase, catalyzing the oxidative deamination of histamine to produce imidazole acetaldehyde and an ammonium ion, and also oxidizing agmatine and putrescine had been reported for *Nocardioides simplex*; the gene encoding this enzyme had been characterized and overexpressed in *Escherichia coli* (Fujieda et al., 2004, 2005; Limburg et al., 2005; Reed et al., 2008; Tsutsumi et al., 2008). Two mycelium-forming strains, *Nocardioides albus* SC13912 (ATCC 55426) and *Nocardioides luteus* SC13911, produce enzymes facilitating the production of a 10-deacetylbaccatin III, a precursor used for semisynthesis of paclitaxel and analogs. An extracellular enzyme from *Nocardioides albus* is a polypeptide (47 kDa) that specifically removes the C-13 side chain from paclitaxel, cephalomannine, and other analogs. An intracellular 10-deacetylase (40 kDa) from *Nocardioides luteus* SC13912 removes the 10-acetate from baccatin III and paclitaxel (Hanson et al., 1994, 2004). *Nocardioides kongjuensis* is able to degrade *N*-hexanoyl-L-homoserine lactone, a signaling molecule in quorum-sensing system of many bacteria (Yoon et al., 2006b). Extremely thermostable deoxycytidine deaminase (52 kDa) with the activity maximum at 99°C was revealed in *Nocardioides* sp., strain CT16 (Sakai et al., 2002). A chitosanase catalyzing the hydrolysis of glycosidic bonds in chitosan and its encoding gene were described for a soil isolate NlO6 identified as *Nocardioides* sp. on chemotaxonomic grounds (Masson et al., 1995). A number of other medically and industrially useful enzymes and degradation activities of *Nocardioides* strains were reported (e.g. Hanson et al., 1994; Jun et al., 1994; Masson et al., 1995; Nishimoto et al., 1996; Nobile and Belleville, 1958; Patel et al., 2000; Siddiqui et al., 2000). Numerous cloning, sequencing, and three-dimensional structure studies of enzymes and relevant genes have been published and the literature and sequences are available from public databases.

Antibiotic sensitivity and antibiotic production. The antibiotic sensitivity and production were determined for some *Nocardioides* species (*Nocardioides aquiterrae*, *Nocardioides aquaticus*, *Nocardioides caricicola*, *Nocardioides daedukensis*, *Nocardioides dokdonensis*, *Nocardioides fonticola*, *Nocardioides hankookensis*, *Nocardioides insulae*, *Nocardioides pyridinolyticus*, and *Nocardioides terrigena*). All strains, except for *Nocardioides pyridinolyticus* (Song et al., 2011) were sensitive to chloramphenicol and streptomycin in different concentrations. Various other antibiotics (ampicillin, carbenicillin, cephalothin, gentamicin, kanamycin, lincomycin, neomycin, novobiocin, oleandomycin, penicillin G, polymyxin B, and tetracycline) suppress growth of individual strains (species) as given in the species descriptions in this chapter. The type strain of *Nocardioides albus* was reported to be highly susceptible to antifungal drugs, such as bifonazole, econazole, miconazole, and clotrimazole, but not to the triazoles fluconazole and voriconazole (100 μg/ml) (Dabbs et al., 2003). No production of β-lactamases associated with resistance to β-lactam antibiotics was revealed for type strains of *Nocardioides albus*, *Nocardioides luteus*, *Nocardioides plantarum*, *Nocardioides pyridinolyticus*, and *Nocardioides simplex* (Ogawara et al., 1999).

The data about antibiotic production of *Nocardioides* strains are relatively sparse as compared with members of some other actinomycete genera. Representatives of *Nocardioides* inhabiting marine shellfish were reported to exhibit wide-spectrum antimicrobial activities and also show antitumor activities (El-Shatoury et al., 2009). Mycelium-forming strains of this genus from wheat roots were capable of suppressing *in vitro* some fungal pathogens of wheat, including *Rhizoctonia solani*, *Pythium* spp., and *Gaeumannomyces graminis* var. *tritici* (Coombs et al., 2004). A *Nocardioides* strain phylogenetically close to *Nocardioides oleivorans* inhibited growth of filamentous fungi (representatives of *Aspergillus* and *Fusarium*) but was not active towards the yeasts or bacteria tested (Romanenko et al., 2008). A strain, identified as *Nocardioides* sp., produces along with known piericidins, a new biologically active 4-pyridinol compound that inhibits NADH dehydrogenase and electron transfer; the new compound inhibited cell division of fertilized starfish (*Asterina pectinifera*) eggs at the minimum inhibitory concentration of 0.09 mg/ml (Kubota et al., 2003). Strains DSM 3176 and DSM 3177 identified as *Nocardioides albus* on morphological and chemotaxonomic grounds have been reported to synthesize leucylblasticidin S, a precursor in the biosynthesis of blasticidin S, as well as to produce a peptidylnucleoside (Dellweg et al., 1988), named rodaplutin (Gullo et al., 1988). They show insecticidal and acaricidal activities, along with weak antimycotic and antibacterial ones (Dellweg et al., 1988). Some strains described under the generic name *Nocardioides* produce macrolide antibiotics, such as luminamicin with activity against anaerobic bacteria (Ōmura et al., 1985), or an antibiotic with antifungal activities against *Candida albicans* and *Candida tropicalis* (Loppinet et al., 1997). Indeed, data on phylogenetic position of some antibiotic-producing strains described in early works under the name *Nocardioides* are not available and some of them (e.g. *Nocardioides* ATCC 39419, a producer of antitumor antibiotic, sandramycin) might not belong to this genus (Matson. and Bush, 1989). This strain had been reclassified as a member of the genus *Kribbella* (Park et al., 1999).

Bacteriophages. A large collection of bacteriophages that multiply in *Nocardioides albus*, *Nocardioides luteus*, *Nocardioides simplex*, and *Nocardioides jensenii* strains but not in strains of other actinomycete genera, including *Aeromicrobium*, have been described (Miller et al., 1991; Prauser, 1976, 1984b; Prauser, 1984a; Prauser, 1989; Prauser and Falta, 1968; Wellington and Williams, 1981; Williams et al., 1980). Some *Streptomyces* phages were reported to cause clearing effects, i.e. phage-dependent lysis without phage propagation, on strains of the species *Nocardioides albus*, *Nocardioides luteus*, and related mycelium-forming organisms of this genus (Prauser, 1976, 1984b, 1989). The sensitivity to specific *Nocardioides* bacteriophages was used to differentiate the *Nocardioides* species from other mycelium-forming actinomycetes (Kurtboke and Williams, 1991; Prauser, 1976, 1984b) and was an additional criterion that justified the transfer of *Arthrobacter simplex* and *Arthrobacter jensenii* to the genus *Nocardioides* (Collins et al., 1989; O'Donnell et al., 1982). The phage susceptibility is considered to rely to a certain degree on

adsorption to specific bacterial cell-wall receptors present in a limited number of closely related bacterial strains (Kurtboke and Williams, 1991; Young, 1967). In the case of the aforementioned *Nocardioides* species and the specific *Nocardioides* phages (Prauser, 1976, 1984b; Prauser, 1984a; Prauser and Falta, 1968), the critical determinants in the initial phage binding site are most likely located on teichoic acids, as reported for representatives of *Bacillus*, *Listeria* and other bacteria (Archibald, 1976; Monteville et al., 1994; Schleifer and Steber, 1974; Wendlinger et al., 1996). Such specific binding sites in strains of *Nocardioides albus*, *Nocardioides luteus*, and related mycelium-forming *Nocardioides* strains may include D-galactose and/or D-glucose linked to pyruvate, which are common structural elements of teichoic acids in these organisms (Shashkov et al., 2000b; Shashkov et al., 1999; Tul'skaya, 2009).

Genomic characteristics and plasmids. The mol% G+C of the DNA of members of this genus is around 70 (Table 215), with a lower value of 66.5 (T_m) reported for strain *Nocardioides albus* IMET 7801 (Prauser, 1976) and a higher value of 74.8 (HPLC) for a strain of *Nocardioides lentus* (Yoon et al., 2006a). Analysis of the 16S–23S rRNA gene's internally transcribed spacer (ITS) region found no tRNA sequences in more than 30 strains of the genus *Nocardioides* and related organisms (Yoon et al., 1998a) in contrast to some other actinomycetes (Baylis and Bibb, 1988; Kim et al., 1993; Normand et al., 1992; Pernodet et al., 1989; Yoon et al., 1997b). Moreover, two types of 16S–23S ITS sequences (differing in size from 1 to 12 bp) were found in a few strains of *Nocardioides albus* (DSM 43874, JCM 5851, and JCM 5862) and the strain *Nocardioides simplex* NCIMB 12919, which suggests that at least two rRNA operons might occur in genomes of these organisms. The 16S–23S ITSs in *Nocardioides* strains vary in size from 328 (*Nocardioides nitrophenolicus*) to 539 bp (the *Nocardioides albus* group). The levels of nucleotide similarity between the type strains ranged from 48.4% (for the pair *Nocardioides jensenii – Nocardioides nitrophenolicus*) or 51.3% (for the pair *Nocardioides jensenii – Nocardioides simplex*) to 84.8% (for the type strains of *Nocardioides albus* and *Nocardioides luteus*). The sequences of *Nocardioides simplex* strains used in the study were identical or nearly identical (386–388 bp) and exhibited a high nucleotide sequence similarity (97.7–100%). The 16S–23S ITSs of the type strain of *Nocardioides luteus* and "*Nocardioides fulvus*" 71-N86 (= IMET 7846 = DSM 46115 = JCM 3335), "*Nocardioides flavus*" 71-N54 (= IMET 7844 = DSM 46114 = NBRC 14396), and 71-N82 (= KCTC 9579 = NBRC 14397) were also identical in size (473 bp) and invariant or almost similar (1 bp difference) in the sequences. The data indicate that these three strains (isolated from soils from different parts of worldwide) are *Nocardioides luteus* (Prauser, 1984a; Ruan and Zhang, 1979; Tille et al., 1978). In contrast, the 18 strains referred to as *Nocardioides albus* substantially differed in the 16S–23S ITS nucleotide sequences, sharing 84.2–100% sequence similarity (the former figure is lower than the value for type strains of this species and *Nocardioides luteus*). They also differed in size of 16S–23S ITS sequences (468–539 bp), with the type strain containing 514 bp and some strains containing 473 bp (identical to that in *Nocardioides luteus*).

The sequences of RNase P RNA genes were analyzed for seven *Nocardioides* species and representatives of other genera (Yoon and Park, 2000). The sequence similarity between the type strains of *Nocardioides* species was 77.6–94.7 (approx. 64–89% if gaps are included). Like its 16S–23S ITS sequences, the RNase P RNA gene sequence of the type strain of *Nocardioides luteus* is identical or almost identical (differing by 1 bp) to the sequences in "*Nocardioides flavus*" 71-N54 and "*Nocardioides fulvus*" 71-N86. Phylogenetic analysis based on RNase P RNA gene sequences showed the clustering of the type strain of *Nocardioides albus* with *Nocardioides luteus* (94% sequence similarity), *Nocardioides simplex* with *Nocardioides nitrophenolicus* (94.7% similarity), and the formation of distinct lineages by other species (*Nocardioides jensenii*, *Nocardioides plantarum* and *Nocardioides pyridinolyticus*). Importantly, the sequence similarity values (77.6–78.6%) between more distant *Nocardioides* species were lower than, or close to, the values between *Nocardioides* species and strains of *Kribbella* (79.3–83.3%) or *Aeromicrobium* (77.4–82.0%). Accordingly, the *Nocardioides* species did not form a coherent cluster in the extended tree including members of these and other genera used in the study. Furthermore, *Luteococcus japonicus* (*Propionibacteriaceae*) possessed a gene with a nucleotide sequence that was nearly identical (>99% similarity) to that of *Nocardioides jensenii* (Yoon and Park, 2000), which suggests that the RNase P RNA gene transfer can take place between these groups.

As mentioned before, *Nocardioides* sp. JS614 is the only completely sequenced member of the genus capable of assimilating vinyl chloride and ethene, and degrading a number of short-chain alkenes (GenBank accession no. NC_008699; Copeland et al., 2006). The genome is a circular molecule (4.99 Mb), which harbors 4546 protein-coding genes and 55 predicted pseudogenes. The circular plasmid pNOCA01 (307,8 bp) of this strain (GenBank accession number CP000508) has the DNA G+C content of 68 mol%, which is lower than that calculated for the genome (71 mol%) and carries genes encoding key enzymes participating in alkene oxidation and assimilation (Chuang and Mattes, 2007; Mattes et al., 2007; Mattes et al., 2003; Mattes et al., 2005). A few other plasmids were also found in *Nocardioides* strains possessing degradative activities. A plasmid with the *dfdBC* gene cluster encoding a ring-cleavage dioxygenase that degrades dibenzofuran (an oxygen-containing heterocyclic compound) was reported for strain *Nocardioides* sp. DF412 (Miyauchi et al., 2008). A plasmid (34.2 kb) bearing genes encoding the sulfur oxidizing enzyme system involved in degradation of dibenzothiophene (an environmentally persistent heterocyclic sulfur compound) was found in *Nocardioides* sp. PKSP 12 (Sandhya et al., 1995, 1997).

Habitat and ecology. Bacteria of the recognized species of the genus *Nocardioides* have been isolated from various environments (Table 215). Numerous ecological studies indicate the presence of these organisms in various terrestrial and aquatic ecosystems worldwide, including low-temperature and deep subsurface ecosystems as well as nutrient-limited environments (e.g. Barton et al., 2007; Boivin-Jahns, et al., 1995; Gontang et al., 2007; Groth and Saiz-Jimenez, 1999; Groth et al., 1999; Katayama et al., 2006; Rintala et al., 2008; Vishnivetskaya et al., 2006; Ward and Bora, 2006; Zhang et al., 2009a). Mycelial *Nocardioides* strains were reported to predominate in kaolin prepared for the ceramic industry (Prauser, 1976, 1986). There is now substantial evidence that representatives of the genus *Nocardioides* also occur in soils and industrial wastewater polluted by different organic and inorganic compounds, including toxic polyaromatics, heavy metals, and nuclear waste (e.g. Coleman et al., 2002; Desantis et al., 2006; Fredrickson et al., 2004;

Futamata et al., 2004; Golovleva et al., 1990; Hamamura and Arp, 2000; Iizuka and Komagata, 1964; Kubota et al., 2005a; Lee et al., 1994, 1991); Maltseva and Oriel, 1997; Männisto et al., 1999; Mattes et al., 2003; Miyauchi et al., 2008; Rajan et al., 1996; Sandhya et al., 1995; Schippers et al., 2005; Suzuki and Komagata, 1983c; Yoon and Park, 2006; Yoon et al., 1999).

Members of the genus *Nocardioides*, like many other actinobacteria, are most likely involved in the turnover of organic matter in ecosystems because they can degrade and metabolize a wide range of natural organic compounds. The ability to degrade aromatic compounds, including polyaromatics and other chemicals, implies a significant role in the natural degradation of such compounds. In organics-limited environments, organisms of this genus, as mentioned before, may use traces of organics dissolved in water or derived from the decomposition of other micro-organisms, or interact mutualistically with other micro-organisms in such environments (Barton et al., 2004; Barton et al., 2007; Groth and Saiz-Jimenez, 1999). Bacteria of the genus *Nocardioides* can also be detected in the water phase of tropospheric clouds (Amato et al., 2006) where they may be active and take part (as described for other bacteria) in the biodegradation of organic compounds dissolved in cloud water, reaching up to 20 mg per liter (Vaitilington et al., 2010). In desert dust clouds, they can migrate great distances through the atmosphere during dust storms (Griffin, 2007; Polymenakou et al., 2008).

All the above data indicate that the resting and/or vegetative cells of organisms of the genus *Nocardioides* can survive and maintain a suitable metabolic activity under extreme conditions such as increased UV and nuclear radiation, and heavy metal or other pollutant contaminations. The data also indicate the high adaptive potential of organisms of this genus. At the genomic level, this potential is often associated with increased numbers of genes in the hypervariable regions, often called "gene islands", and the ability to move horizontally (Dobrindt et al., 2004; Wilmes et al., 2009). In the latter context, it might be relevant to note that thin channel-like structures connecting cells of *Nocardioides* are occasionally seen on electron micrographs.

Bacteria of this genus occur in the rhizosphere, roots, and the above-ground parts of plants; some have been reported to be mutualistic plant endophytes (Coombs and Franco, 2003; Coombs et al., 2004; Qin et al., 2009; Song et al., 2011; Tian, 2007; Ulrich et al., 2008). Similar to other endophytic bacteria, they may obtain nutrients from plants, obtain protection from abiotic stress like desiccation or freezing, promote plant growth via different mechanisms, and prevent plant disease caused by plant-pathogenic bacteria, fungi, and insects by secreting secondary metabolites (Coombs and Franco, 2003; Dimock et al., 1988; Firakova et al., 2007; Hallmann et al., 1997; Kloepper et al., 1991; Reiter et al., 2002; Schrey et al., 2005; Tian et al., 2007; Tian et al., 2004). Members of this genus can also be found in association with lichens, daphnia, termites and other eukaryotic organisms, including vertebrates and humans (e.g. Delbes et al., 2007; El-Shatoury et al., 2009; Fall et al., 2007; Grice et al., 2009; Li et al., 2007b; Tóth et al., 2008). Although bacteria of the genus *Nocardioides* have been occasionally found in bacterial populations associated with human diseases (Cox et al., 2003; Frank et al., 2007; Harris et al., 2007), they are considered non-pathogenic either to humans or other warm-blooded animals.

Enrichment and isolation procedures

Most *Nocardioides* strains have been isolated at random from terrestrial or marine environments during studies of bacterial diversity in certain biotopes or during screening for strains possessing biodegradative activities. Organic media with low nutrient concentrations are generally advantageous for recovering diverse *Nocardioides* species from natural habitats. *Nocardioides* strains are successfully isolated by the standard dilution plating technique on suitable nonselective ("total count") agar media including the standard R2A agar (Difco), twofold or tenfold-diluted R2A, tenfold-diluted nutrient agar (NA, Difco), oligotrophic medium PYGV (Staley, 1968) and other media (see, e.g. Prauser, 1976; Yoon and Park, 2006), and the descriptions of *Nocardioides* species in this chapter). Oligotrophic medium PYGV (Staley, 1968) with sea water(Lawson et al., 2000a), marine agar (Difco), and a number of other nutrient media supplemented with sea water or salts in a proper concentration (Choi et al., 2007; Lee, 2007a; Park et al., 2008; Yi and Chun, 2004b, a) can be used for isolation of *Nocardioides* strains from marine ecosystems or other hypersaline environments. For isolation of *Nocardioides* strains from alkaline soil, a diluted nutrient agar (NA; Difco) with the pH adjusted to 9.0–10.0 using Na_2CO_3 can be applied (Yoon et al., 2005a; Yoon et al., 2005b; Yoon et al., 2005d, 2006a). *Nocardioides* can also be isolated using media and procedures recommended for arthrobacters (Keddie et al., 1986) and some rhodococci (Goodfellow and Maldonado, 2006).

Since the cells or mycelium fragments are usually closely associated with the mineral and organic particles of the soil, a special procedure for their suspending may be useful, e.g. vigorous shaking of the sample with diluent or mechanical or chemical desorption methods [see Futamata et al. (2004), Herron and Wellington (1990), and Kämpfer (2006), for details and references]. Soil samples pretreated with electric pulses (at a field intensity of 16 kV/cm^2) can result in a highly selective outgrowth of filamentous *Nocardioides*-like strains (Bulina et al., 1998). A subsequent treatment of sample suspension and plating procedures are generally similar to those reported for other mycelial and coryneform actinomycetes [see, e.g. Kämpfer (2006), and Keddie et al. (1986), for details and references]. Isolation of endophytic representatives of *Nocardioides* is carried out from the thoroughly washed and surface-sterilized roots or other parts of plants as described (e.g. Coombs and Franco, 2003; Chung et al., 2008; Song et al., 2011; Tian et al., 2004; Zinniel et al., 2002; or in other works dealing with isolation of plant endophytes). Nutrient-poor media such as humic acid-vitamin B agar (HV; Hayakawa and Nonomura, 1987), tap water-yeast extract agar (TWYE, containing 0.25 g of yeast extract, 0.5 g of K_2HPO_4, and 18 g of agar per liter of tap water) (Crawford et al., 1993), yeast extract-casein hydrolysate agar (YECD, containing 0.3 g of yeast extract, 0.3 g of D-glucose, 2 g of K_2HPO_4, and 18 g of agar per liter of distilled water) (Coombs and Franco, 2003) were successfully applied to isolate endophytic *Nocardioides* from wheat roots. To control fungal growth, the above media can be supplemented with 50 µg/ml benomyl (DuPont). Other antibacterial and antifungal agents might be helpful, but some, including antifungal agents (Dabbs et al., 2003) may inhibit the growth of *Nocardioides* organisms.

Selective enrichment procedures and special media containing certain synthetic organic chemicals (pollutants) or their derivatives are advantageous for isolation of *Nocardioides* strains from polluted environments. Such procedures and media were reported while isolating strains of *Nocardioides pyridinolyticus* (Yoon et al., 1997b), *Nocardioides nitrophenolicus* (Yoon et al., 1999), *Nocardioides aromaticivorans* (Kubota et al., 2005a), *Nocardioides simplex* ("*Brevibacterium lipolyticum*") (Iizuka and Komagata, 1964), *Nocardioides oleivorans* (Schippers et al., 2005), and a number of other not yet named representatives of the genus (e.g. Maltseva and Oriel, 1997; Männisto et al., 1999; Mattes et al., 2003; Miyauchi et al., 2008; Rajan et al., 1996). Because organisms of this genus may be sufficiently adapted to the environmental conditions, isolation conditions may be employed that mimic natural environmental conditions. While intended for isolation of strains belonging to or closely related to the described *Nocardioides* species, the selective (semi-selective) media may be prepared taking into account isolation sources and the specific characteristics listed in Table 215 and mentioned in the species description.

Incubation of isolation plates or enrichment cultures is usually carried out at 25–30°C for an appropriate time period, but may also be carried out at a lower (10–15°C) or higher (40°C) temperature (Iwabuchi et al., 1998; Kim et al., 2008a; Lawson et al., 2000a). Colonies of mycelium-producing *Nocardioides* strains formed on many isolation media can be distinguished from those of other actinomycetes (mostly streptomycetes that are abundantly present in the same soil sample) based on the absence of mycelium or scant aerial mycelium, pasty or sand-pasty consistency of colonies, and whitish, light creamy-white, yellowish-white, or yellow colony color. These features, however, are also characteristic of representatives of some other nocardioform actinomycetes, including *Agromyces*, *Kribbella*, or *Promicromonospora* often present in the same soil sample. The *Nocardioides* species with rod-shaped cell morphologies usually occur among coryneform soil isolates that have slender cells and white, yellowish, or indistinctly pigmented colonies.

Maintenance procedures

Cultures may be maintained as 20% glycerol suspensions at −20 and −80°C. Long-term conservation is achieved by freeze-drying or in liquid nitrogen by standard procedures.

Differentiation of the genus *Nocardioides* from other genera

The characteristics essential for phenotypic delineation of the currently recognized genus *Nocardioides* are listed in Table 214 and Table 216. The major menaquinone MK-8(H_4) is the most prominent chemotaxonomic marker that differentiates members of the genus *Nocardioides* from all other genera of the family, except for *Marmoricola*. The presence of well-developed branching hyphae or relatively long rods (in young cultures), along with a marked rod-to-coccoid morphogenetic life cycle, allows primary separation of the majority of *Nocardioides* species from members of the genus *Marmoricola*, which typically produce spherical cells. Genus level identification of novel strains that form short rods to coccoid cells in young cultures or exhibit to a greater or lesser extent phylogenetic relatedness to the genus *Marmoricola* and related *Nocardioides* species is achieved (in the current classification system) via comparison of such strains with respective individual species of these genera (Table 216). The data on cellular fatty acids are of a practical importance, along with other phenotypic characteristics (Table 214 and Table 216).

Taxonomic comments

The genus *Nocardioides*, with the type species *Nocardioides albus*, originally encompassed the actinomycetes that produced branched fragmenting hyphae, possessed the peptidoglycan type similar to that of the genus *Streptomyces*, and showed susceptibility to specific actinophages (Prauser, 1976). The second mycelium-forming species, *Nocardioides luteus*, was added to the genus in 1984 (Prauser, 1984b, 1985). Shortly before, O'Donnell et al. (1982, 1983) reclassified *Arthrobacter simplex*, which was first described as *Corynebacterium simplex* (Jensen, 1934) and then affiliated to the genus *Arthrobacter* (Lochhead, 1957), as *Nocardioides simplex*. There was general agreement by 1982, mainly on chemotaxonomic grounds, that atypical LL-A_2pm-containing arthrobacters should be removed from this genus (for further details and references, see, e.g. Keddie and Jones, 1981; Keddie et al., 1986; Suzuki and Komagata, 1983c). The distant relatedness of *Arthrobacter simplex* to *Arthrobacter globiformis* was also shown by the rRNA cataloguing studies (Stackebrandt et al., 1980). However, the LL-A_2pm-containing arthrobacters remained species "in search of a genus" at that time.

The proposal of O'Donnell et al. (1982, 1983) to affiliate *Arthrobacter simplex* to *Nocardioides* was based on similarity of the type strain of this species to the mycelium-forming *Nocardioides* in lipid composition (fatty acids, phospholipids, and menaquinones), as well as on other supportive data including, in particular, data on the presence the peptidoglycan type A3γ (Prauser, 1978; Schleifer and Kandler, 1972), the sensitivity to some of specific *Nocardioides* actinophages (Prauser, 1976, 1981; Wellington and Williams, 1981), the DNA G+C content (Tille et al., 1978; Yamada and Komagata, 1970), and the DNA–DNA similarity level of 15–20% (Prauser, 1981). While discussing the generic affiliation of coryneform *Arthrobacter simplex* to *Nocardioides*, O'Donnell et al. (1982) also referred to some actinomycete genera that accommodate morphologically diverse strains and to the evidence from early 16S rRNA sequencing studies (Stackebrandt et al., 1980; Stackebrandt and Woese, 1981) that morphological properties are not always reliable indicators of natural relationships.

Owing to the inclusion of *Arthrobacter simplex* into *Nocardioides* (the transfer was validated in 1983), the genus became heterogeneous with respect to morphology. The authors proposed the emended description of the genus *Nocardioides* with inclusion of the extended range of morphological and chemotaxonomic characters (O'Donnell et al., 1982). This proposal, however, was not validated. There were conflicting opinions with regard to the assignment of organisms with markedly different morphology to one genus, mainly for practical reasons prevailing at that time. The aggregation of a typical nocardioform organism with abundant primary and aerial mycelium (*Nocardioides albus*) with a motile, single-celled bacterium (*Arthrobacter simplex*) was questioned, in particular, by the author of the genus *Nocardioides*, H. Prauser (Prauser, 1986). In line with this view, Suzuki and Komagata (1983b, 1983c) validly published the new genus *Pimelobacter* to accommodate some LL-A_2pm-containing

[a]Data are for the type strains. Symbols and abbreviations: +, positive; −, negative; w, weak; v, variable or conflicting data; nd, no data available; UL, unknown polar lipid(s); PL, unidentified phospholipids(s); other abbreviations, see also Table 215.

[b]Data are from Suzuki and Komagata (1983c), Yi and Chun (2004a), Dastager et al. (2008d, 2008f, 2010), Lee (2007a), Urzì et al. (2000), Yoon et al. (2005a, 2005d, 2010), Tóth et al. (2008), Lee and Lee (2010), and Lee et al. (2010).

[c]See Figure 248 and Figure 247 for phylogenetic position of the organisms.

[d]Differences in the color intensity and shade and the cell appearance may be influenced by the growth conditions and culture age.

[e]Older cultures of *Nocardioides* species as a rule consist of short rods, coco-bacillary and/or coccoid forms.

[f]Tolerance to NaCl and pH and optimal pH values for growth may vary depending on the test medium composition (mineral, rich in organics, liquid and/or agar-containing).

[g]*NA*, nutrient agar (Difco); *R2A*, R2A agar (Difco); *1/2 R2A*, half-strength R2A agar (1.6 g of R2A broth powder supplemented with 1.5% agar in 1 l of distilled water); *TSA*, trypticase soy agar (Difco); *TSB*, trypticase soy broth (Difco).

[h]DNA base composition as determined by the HPLC method; data for *Nocardioides jensenii* were estimated by the thermal denaturation method.

arthrobacters. Pointing out a rather close relatedness of the studied atypical arthrobacters to *Nocardioides albus* in chemotaxonomic characteristics along with a dissimilarity in the cell morphology and colony appearance, the authors noted some difference between these organisms in the fatty acid and menaquinone composition, a higher DNA G+C content in strains assigned to *Pimelobacter*, and low DNA–DNA similarity values clearly showing distant relationship of *Nocardioides albus* and *Pimelobacter* (Suzuki and Komagata, 1983c). The following species were included in the genus: the type species *Pimelobacter simplex* (*Arthrobacter simplex*), *Pimelobacter jensenii* (created for a single strain NCMB 9770 = JCM 1364, formerly a strain of *Arthrobacter simplex*; Jensen and Gundersen, 1956), and *Pimelobacter tumescens* (the former *Arthrobacter tumescens*; Jensen, 1934; Conn and Dimmick, 1947) currently belonging to the genus *Terrabacter* (see below).

Thus, the valid descriptions of *Arthrobacter simplex* (Lochhead, 1957), *Nocardioides simplex* (O'Donnell et al., 1982, 1983), and *Pimelobacter simplex* (Suzuki and Komagata, 1983a, 1983c) are based on the same type strain and their names are considered to be objective synonyms, with *Arthrobacter simplex* being basonym. In the first edition of *Bergey's Manual of Systematic Bacteriology*, this species was treated under *Arthrobacter*, in Addendum II to "The list of species of the genus *Arthrobacter*", mentioning *Nocardioides simplex* and *Pimelobacter simplex* in the list of synonyms and emphasizing that "the taxonomic position of *Arthrobacter simplex* (and *Arthrobacter tumescens*) remains unresolved" (Keddie et al., 1986). The species *Pimelobacter jensenii* was briefly discussed in the *Further comments* to the description of *Arthrobacter simplex* (Keddie et al., 1986).

Subsequent taxonomic study of the above group using the 16S rRNA-based phylogenetic analysis showed that *Nocardioides albus*, *Nocardioides luteus*, *Nocardioides* (*Pimelobacter*) *simplex*, and *Pimelobacter jensenii* formed a coherent phylogenetic cluster among the strains included in the study, whereas *Pimelobacter tumescens* was phylogenetically distinct (Collins et al., 1989). Accordingly, *Pimelobacter jensenii* was transferred to the genus *Nocardioides*, while *Pimelobacter tumescens* was reclassified as a representative of the newly established genus *Terrabacter* (in the family *Intrasporangiaceae*). Shortly thereafter, Collins and Stackebrandt (1989a, 1989b) proposed the new species *Nocardioides fastidiosus* that seemed at that time to be phylogenetically affiliated to the genus *Nocardioides*. This species was later transferred by Tamura and Yokota (1994) to the genus *Aeromicrobium* (Miller et al., 1991).

Proposals of all other *Nocardioides* species published within the period 1994–2010 and described in this volume rely on the 16S RNA-based phylogenetic analysis, key chemotaxonomic characteristics as well as differences from related species in phenotypic traits and DNA–DNA hybridization values (currently accepted for species delineation) (Stackebrandt et al., 2002; Wayne et al., 1987). The DNA–DNA hybridization experiments (mostly by the method of Ezaki et al., 1989) were performed mainly when particular strains and closely related organisms had high 16S rRNA sequence similarities. However, DNA–DNA hybridization values or other data justifying delineation at the genomic level from the closest related species are absent in a few cases. These mostly include species proposed independently and almost at the same time by different research groups.

At present the genus *Nocardioides* displays an assemblage of phylogenetically rather distant and phenotypically dissimilar species whose features are not reflected by the original genus description created for mycelium-forming actinomycetes (Prauser, 1976). The most unrelated species share 92–93% sequence similarities which are equal to or even less than values separating the well-defined genera in the family *Nocardioidaceae* and other families of the suborder *Actinomycetales*. In addition, as stated before, the differences in both 16S–23S ITS and RNase P gene sequence similarities between some *Nocardioides* species are less than those between some *Nocardioides* species and representatives of other actinomycete genera used in the study (Yoon et al., 1998a; Yoon and Park, 2000).

At the chemotaxonomic level, there are only two characteristics identical for all *Nocardioides* species, i.e. the presence of LL-A_2pm in the cell-wall peptidoglycan and the predominance of the menaquinone MK-8(H_4). Both these characteristics are also typical of some other actinomycete genera (e.g. in the family *Intrasporangiaceae*). In general, *Nocardioides* species seem to display a common fatty acid type, the complex fatty acid type *sensu* Suzuki et al. (1993) and type 3 according to Kroppenstedt (1985). However, it appears that several different subtypes may be distinguished. The data on other chemotaxonomic features are absent for most *Nocardioides* species; if reported, do not appear to be uniform. In particular, the phospholipid types, I, II, and III (with no nitrogenous phospholipids or with phosphatidylethanolamine and phosphatidylcholine as diagnostic components) are usually considered to represent chemotaxonomic markers useful in distinguishing actinomycete genera (Kämpfer, 2006; Kroppenstedt and Evtushenko, 2006; Kroppenstedt and Goodfellow, 2006; Lechevalier et al., 1977, 1981). On the other hand, some specific component(s), e.g. an acylphosphatidylglycerol-like phospholipid (PL_1 in Figure 263) are variable among *Nocardioides* species with the phospholipid type I. Some representatives of this genus also differ in the composition of peptidoglycan-bound cell-polymers (Shashkov et al., 1999, 2000b; Tul'skaya, 2009), and in polyamine patterns (Busse and Schumann, 1999). Furthermore, the cell-wall peptidoglycan structure (undetermined for the majority of *Nocardioides* species) might turn out to be dissimilar in some phylogenetically distant organisms of this genus. This has been shown, in particular, for some LL-A_2pm-containing organisms of the family *Propionibacteriaceae* (the sister family of the *Nocardioidaceae*) and for members of the family *Intrasporangiaceae* (see Schumann et al., 1997, 2009; Stackebrandt and Schaal, 2006; and the respective chapters in this volume). The acyl type of muramic acid, a characteristic feature of the cell envelope differentiating some genera within a family or a suborder (Uchida and Seino, 1997), might be dissimilar for distantly related *Nocardioides* species as well. Organisms of the genus *Nocardioides*, as mentioned before, also differ in cell morphology, catalase activity (a possible indication that different factors are utilized to prevent oxygen damage or cope with certain environmental conditions), optimal and maximal salinity for growth, pH growth range, and other properties affected by ecological niche and in turn affecting speciation.

The data available suggest that further taxonomic study of *Nocardioides*, involving the data on genomics and proteomics, will result in the dissection of this genus into several genera and the establishment of phenotypically and phylogenetically coherent taxa. Dissection of the genus *Nocardioides* is consistent with the current trend toward improving the classification

schemes of heterogeneous actinomycete genera, e.g. by finding of additional phenotypic (chemotaxonomic) differentiating characteristics and establishing novel genera (see recent publications in IJSEM). Dissection is also in line with a tendency to describe novel species (often originating from the same or similar ecological niches) that show very high 16S rRNA gene sequence (99% and higher) and include strains exhibiting greater genomic and phenotypic homogeneity. Finally, the classification system must take into account ecological studies revealing diverse novel organisms associated with, or belonging to, the recent genus *Nocardioides* and showing high 16S rRNA gene sequence similarity to species of this genus.

At the moment, some recognized *Nocardioides* species need to be revised taking into account their more focused circumscriptions and current taxonomic concepts. Prominent examples of such species requiring further revision and emendation of the species description are *Nocardioides albus* Prauser 1976 and *Nocardioides luteus* Prauser 1984b. According to the original description of *Nocardioides albus*, based on the study of 17 strains from a variety of soils and related sources from different sites of the world (Prauser, 1976), the species encompassed strains showing a certain phenotypic similarity, mostly in formation of indistinctly colored (whitish to faintly yellowish or faintly brownish) primary mycelium and white aerial mycelium. The species *Nocardioides luteus* was proposed to accommodate strains distinguished by distinct yellow to orange-yellow primary mycelium and cream aerial mycelium (when well developed) (Prauser, 1984b). The separate species status of these organisms was justified by DNA–DNA hybridization experiments with the type strains of the two above species. However, relatedness to *Nocardioides albus* of the remaining strains studied in the original work (Prauser, 1976) and also many other mycelial organisms later described in the literature under the species names *Nocardioides albus* (Collins et al., 1994; Evtushenko and Zelenkova, 1989; Prauser, 1976; Suzuki and Komagata, 1983c; Yoon et al., 1998a; Yoon et al., 1998b) has not been verified in by DNA–DNA hybridization experiments or other adequate genomic analysis. An exception is *Nocardioides albus* IMET 7832 with a high DNA–DNA relatedness to the type strain (Prauser, 1984b) and probably some strains that harbor 16S rRNA gene and 16S–23S ITS sequences identical or almost identical to those of the type strain (Yoon et al., 1998a; Yoon et al., 1998b).

Meanwhile, much evidence has accumulated showing that strains referred to as *Nocardioides albus* are heterogeneous group. As mentioned before, some strains of this assemblage are affiliated with *Nocardioides luteus* or distinct from *Nocardioides albus* or *Nocardioides luteus* on the basis of 16S rRNA gene and 16S–23S rDNA ITS sequence analyses (Yoon et al., 1998a, 1998b). Some were found to contain teichoic acids identical to those of the type strain of *Nocardioides luteus* or differ from those of both the *Nocardioides luteus* and *Nocardioides albus* type strains (Tul'skaya, 2009). Differences in susceptibility to individual actinophages (Prauser, 1976) might indicate differences in cell-wall chemistry between strains of the *Nocardioides albus* complex. Representatives of this group tend also to differ from the *Nocardioides albus* type strain in the proportions of the predominant polyamines (Busse and Schumann, 1999). There is also a report of one *Nocardioides albus* strain (IMET 7819) with a fatty acid composition anomalous to that of the type and other strains studied under the same experimental conditions (O'Donnell et al., 1982). In addition, there are some differences in physiological characteristics, including the range of pH and NaCl concentration for growth (Prauser, 1976; Suzuki and Komagata, 1983c; L. Dorofeeva and L. Evtushenko, unpublished). Some strains of the *Nocardioides albus* assemblage might be eventually be proven to be *Nocardioides luteus* strains and described as non-pigmented subspecies (biovars), while other strains most likely will be assigned to novel species.

Another group of *Nocardioides* species in need of further attention includes a few recent species proposed shortly after the description of their phylogenetic relatives. For such strains, the DNA–DNA hybridization or other relevant experiments justifying their separation into species at the genomic level were not performed. As an example, *Nocardioides basaltis* (Kim et al., 2009a) is closely related to *Nocardioides salarius* (Kim et al., 2008a) (Figure 248). Both these species have very similar fatty acid profiles and other phenotypic traits (Table 215) and originate from marine-related environments in the same geographic region. In this context it is worth noting that many bacteria including actinomycetes have more than one rRNA operon and multiple 16S rRNA gene variants (Acinas et al., 2004). The difference between 16S rRNA genes in one genome may range from 0 to several percent (Conville and Witebsky, 2007; Wang et al., 1997; Yap et al., 1999). In the case of *Nocardioides* species, at least two rRNA operons with two types of 16S–23S ITS sequences (differing in size by up to 12 bp) may occur in some strains (Yoon et al., 1998a). Analogously, other organisms of this genus may contain more than one rRNA operon, which may include 16S rRNA genes with substantially different sequences. Accordingly, the species status of organisms, which is mostly based on direct 16S rRNA sequencing of a single isolate, might be ambiguous (particularly taking into account the limitations of measuring DNA–DNA relatedness by the hybridization technique and of delineating phenotypic features with certainty). The *Nocardioides* strains in assemblages in need of further attention include those very similar in phenotypic traits and isolated from the same or similar ecological niches located at the same or nearby geographical sites. Further comparative taxonomic studies of such species and newly isolated strains, utilizing 16S rRNA gene sequence analysis and reanalysis, with cloning and evaluation for the presence of multiple copies of this gene as well as multilocus sequence analysis (MLSA; Gevers et al., 2005; Rong and Huang, 2010) would help clarify the taxonomy of this genus.

Differentiation of the species of the genus *Nocardioides*

The phenotypic properties differentiating species of the genus *Nocardioides* are listed in Table 215, Table 216, Table 217, Table 218, Table 219, and Table 220. Additional details are given in the *List of species of the genus Nocardioides*.

Assignment of a previously unknown or a dubious isolate to a certain species normally is a two-stage process. In the first stage, the strain in question is assigned to a certain genus; in the second stage, the species level is identified. During stage one the data from phylogenetic analyses are matched to a spectrum

[a]Data presented are for the type strains. Symbols and abbreviations: +, positive; −, negative; (+), weakly positive; nd, no data available; MW, milky white; GY, grayish yellow; YW, yellowish white; W, white.

[b]Data from Yoon et al. (2006b, 2009), Kubota et al. (2005a), Suzuki and Komagata (1983c), Yi and Chun (2004a), Cui et al. (2009) and unpublished data of the authors of this chapter.

[c]Some variation in the color shade and intensity may be influenced by the growth conditions and culture age.

[d]Negative reaction was reported by Yi and Chun (2004a).

[e]Data on carbon source utilization for all species, except for *Nocardioides ginsengisoli* according to the API 50 CH test system (bioMérieux), with the AUX (bioMérieux) used as the inoculation medium (Yoon et al., 2009). Data for *Nocardioides ginsengisoli* and some data for other species (except for *Nocardioides caeni*) were also obtained using a mineral salts medium supplemented with vitamins and trace element solution as the basal medium (Cui et al., 2009).

[f]Positive results were reported by Cui et al. (2009).

[g]Data from Cui et al. (2009).

[h]Weak activity was reported by Yi and Chun (2004b).

TABLE 219. Percentage cellular fatty acid compositions of the type strains of the *Nocardioides simplex* assemblage[a]

Fatty acid	*N. aromaticiborans*[b]	*N. ginsengisoli*[b]	*N. kongjuensis*[b]	*N. nitrophenolicus*[b]	*N. simplex*[b]	*N. caeni*[c]

[a]Fatty acids that represented <1% in all strains are omitted (except for $C_{17:0}$ anteiso.and $C_{17:0}$ 10-methyl for *Nocardioides caeni*).

[b]Data from Cui et al. (2009). Fatty acids as determined in cell mass harvested from trypticase soy agar (TSA; Difco) after incubation at 30°C for 2 d.

[c]Data from Yoon et al. (2009). Fatty acids as determined in cell mass harvested from nutrient agar (Difco) after incubation at 30°C for 7 d (different proportions of fatty acids will be obtained for this strain if grown on TSA for 2 d).

of phenotypic characters identified with a supposedly coherent group bearing the genus name. During stage two, characters said to be associated with the genus taxon but in a less consistent way may be the focus of attention. Sometimes the results of such a preliminary screening provides useful hints to help further the species level differentiation. In particular, the morphological features (extensively branched hyphae or rod-shaped cells) and chemotaxonomic traits (fatty acid composition, polar lipids, cell-wall polysaccharides, and polyamine patterns) are helpful. Strains phylogenetically related to the *Marmoricola* species require special attention (Figure 247 and Figure 248). The morphological, chemotaxonomic, and other phenotypic characteristics distinguishing *Nocardioides* and *Marmoricola*-related organisms is of practical significance and some key characteristics are given in Table 216.

Strains can be preliminarily assigned to *Nocardioides* species or species group using the multiplex PCR assay and specific primers generated by aligning 16S rRNA gene sequences of *Nocardioides* and one universal reverse primer (Park et al., 1998). Most *Nocardioides* species were described on the basis of a single isolate designated the type strain. Therefore, the other members of such species might differ in some growth and physiological features from the type strains. In addition, some enzymes are inducible, so the test results for enzymic activities (and some other phenotypic characteristics) may be influenced by the medium used to obtain the cells used in a particular experiment. Moreover, the type and reference strains maintained for many years in culture collections might have characteristics altered to some extent since their isolation. A prominent example is the strain IMET 7801 that lost the ability to produce aerial mycelium (Prauser, 1976; Vandamme et al., 1996). In light of very close 16S rRNA gene relatedness and phenotypic similarity of some species, the precise affiliation of a novel strain with a recognized *Nocardioides* species or its classification as a representative of a novel species requires thorough comparison of phenotypic characteristics and DNA–DNA hybridization results or analyses of other adequate genomic characteristics capable of taxonomic resolution at the strain-species level (Gevers et al., 2005; Rong and Huang, 2010; Rosselló-Mora and Amann, 2001; Schumann et al., 2009). Analysis of the 16S–23S rRNA gene internal transcribed spacer region (Yoon et al., 1998a), RNase P RNA gene (Yoon and Park, 2000), or *gyrB* gene (encoding the β-subunit of DNA gyrase, a type II DNA topoisomerase) for novel strains and related species may facilitate the affiliation strains to species. Correlation between the DNA–DNA similarity level and the *gyrB*-based genetic distance was demonstrated for species of the related genus *Kribbella* (Kirby et al., 2010).

[a]Data are for the type strains. Symbols and abbreviations: +, positive; −, negative; (+), weakly positive; nd, no data available; I, ivory; O, orange; YW, yellowish white; W, white.

[b]Data from Yi and Chun (2004a), Schippers et al. (2005), Li et al. (2007b), Lee (2007b), and Lee et al. (2008).

[c]Some variation in the color shade and intensity may be influenced by the growth conditions and culture age.

[d]No data are available on the ability to grow at a higher concentration of NaCl.

[e]Data on utilization of carbon sources for *Nocardioides exalbidus* are according to the *API CH50* test system (Li et al., 2007a). Data for the remaining species are according to conventional methods (see Table 215 and the original species description for the basal media employed, as well as for the other methods).

[f]Positive result was reported by Lee (2007b).

[g]Activity may be weak (Lee et al., 2008).

[h]Weak activity may be observed (Li et al., 2007b).

List of species of the genus *Nocardioides*

1. **Nocardioides albus** Prauser 1976, 61[AL]

al′bus. L. masc. adj. *albus* white, referring to the white aerial mycelium.

Characteristics are as described for the genus and listed in Table 215. Additional information given below is taken from the works of Prauser (1976, 1989) and Yi and Chun (2004a), unless indicated.

Primary mycelium is white or may be whitish to faintly cream-colored in aged cultures on some ISP media, including glycerol-nitrate agar. White aerial mycelium is typically well formed on yeast extract-malt extract agar, oatmeal agar, chitin agar, and glucose-asparagine agar (Figure 251 and Figure 252); usually fairly well formed on inorganic salts-starch agar and glycerol-asparagine agar, and absent on glycerol-nitrate agar and many complex media rich in organics. No distinct soluble pigments are usually produced. Colonies lacking aerial mycelium are mostly pasty, with smooth to wrinkled and dull to bright surfaces. Growth is optimum at about 28°C, good at 10°C and 37°C, but not at 50°C; weak growth may occur at 42°C. Grows in up to 8% (w/v) NaCl and at initial pH 6–9; weak growth may be observable at initial pH 5 and 10, as assessed in PYGP medium containing 0.5% peptone, 0.3% yeast extract, 0.5% glucose, and 0.02% K_2HPO_4 (L. Dorofeeva and L. Evtushenko, unpublished data). Nutritionally non-exacting; grows well on a suitable mineral salts medium with glucose as sole carbon-plus-energy source and an ammonium salt or nitrate as sole nitrogen source. Growth and biomass production are enhanced in the presence of vitamins (Lawson et al., 2000a) and traces of organics. Utilization of some sugars may depend on the presence of vitamins; thiamine supports growth with D-mannitol, while a solution of vitamins (thiamine, riboflavin, nicotinic acid, pyridoxine and *p*-aminobenzoic acid) supports growth on L-rhamnose or D-xylose (Suzuki and Komagata, 1983c). The type strain utilizes succinate, L-asparagine (weak), L-ornithine (weak), and *N*-acetylglucosamine (weak), but not acetamide, L-arginine, L-lysine, and D-sorbitol as sole carbon sources. The ability to use azelate, malonate, suberate, L-proline, histamine, and

tetradecane as sole carbon and energy sources was reported (Collins et al., 1994). Acetate, citrate, and benzoate are utilized, but the test results may vary between test methods (Park et al., 1999; Yi and Chun, 2004a). Acid is produced by oxidation of D-glucose, L-arabinose, sucrose, D-xylose, D-mannitol, D-fructose and L-rhamnose in conventional tests, but not from inositol and raffinose. However, acid was not produced from glucose using the API 20NE test system. No distinct reaction is usually observable in the test for oxidase activity (assessed with tetramethyl-*p*-phenylenediamine). The type strain degrades chitin and grows on chitin agar (Prauser, 1976) as a sole source of carbon and nitrogen. The type strain is highly susceptible to antifungal drugs such as the imidazoles (bifonazole, econazole, miconazole, and clotrimazole), while resistant to triazoles fluconazole and voriconazole (100 μg/ml) (Dabbs et al., 2003).

Peptidoglycan type is A3γ (LL-A_2pm-glycine). The cell-wall sugars are galactose and glucose. The cell wall of the type strain contains poly(galactosylglycerol phosphate) teichoic acid, each monomeric unit containing glycerol, galactose, glucose, pyruvate, and phosphate (Shashkov et al., 1999). The presence of glycerol in the cell wall is the most salient characteristic differentiating this species from *Nocardioides luteus* with cell wall containing ribitol-based teichoic acid (Shashkov et al., 1999, 2000b). The polyamine pattern of the type strain of *Nocardioides albus* grown in rich medium (Yamada and Komagata, 1972) contains almost equal amounts of diamines cadaverine and putrescine (49.0 and 49.6%, respectively), with a minor quantities (<1%) of 1,3-diaminopropane and tyramine, and traces of spermidine and spermine (Busse and Schumann, 1999). The predominant isoprenoid quinone is MK-8(H_4); minor amounts of MK-8(H_2) and MK-8 are detected (Collins et al., 1983; O'Donnell et al., 1982; Suzuki and Komagata, 1983c). The cellular fatty acid profile to a large extent depends on the growth conditions and analytical procedures, but $C_{16:0}$ iso is typically predominating (25–71%) and hydroxylated acids are not detected (Collins et al., 1983; Lee et al., 2000; Miller et al., 1991; Schumann et al., 1997; Suzuki and Komagata, 1983c; Yoon et al., 1997a). The major fatty acids of cells harvested from Nutrient agar (Difco) after 4 d incubation at 30°C were $C_{16:0}$ iso (53.6%), $C_{17:1}$ ω6*c* (15.6%), and $C_{17:0}$ 10-methyl (12.2%); other acids included tuberculostearic acid (TBSA; 2.3%) and homologous components, as well as saturated, unsaturated, iso-, and anteiso- branched acids (Yoon et al., 1997b). The fatty acids of the type strain grown in trypticase soy broth at 28°C for 24–48 h contained mainly $C_{16:0}$ iso (70.8%), along with small proportions of other fatty acids, including TBSA (2.6%) (Schumann et al., 1997). A larger proportion of TBSA (18.3%) was detected in cells from modified Sauton's medium (30°C; Mordarska et al., 1972); $C_{16:0}$ iso contributed 26.6% (O'Donnell et al., 1982). A higher level of TBSA, 34%, was reported by Lee et al. (2000). The qualitative and quantitative composition of polar lipids is also influenced by culture conditions, but phosphatidyl glycerol (PG), diphosphatidyl glycerol (DPG), phosphatidyl inositol (PI) as well as phospholipid (PL_1) [corresponding to acyl phosphatidyl glycerol (APG) in chromatographic behavior] and PI-OH (supposedly a hydroxylated PI) are usually among the principal phosphorous-containing components. Glycolipids may be detected in significant amounts (see the section *Further descriptive information* and Figure 263). Susceptible to specific *Nocardioides* actinophages. The DNA–DNA similarity of the type strain of *Nocardioides albus* to the type strain of *Nocardioides luteus* was 49% and 38% in different experiments (Prauser, 1984b, 1989). Typically occur in soil. The type strain of *Nocardioides albus* was isolated on asparagine agar, containing asparagine 1.0 g, glucose 10.0 g, K_2HPO_4 (anhyd.) 1.0 g, $MgSO_4$ (anhyd.) 0.5 g, NaCl 0.5 g, agar 20.0 g and distilled water 1 liter; pH 7.0–7.2 (Prauser, 1976).

Source (type strain): soil of a lavender field, Tihany peninsula, Balaton region, Hungary.

DNA G+C content (mol%): 68.6 (T_m) (for the type strain; Suzuki and Komagata, 1983c).

Type strain: IMET 7807, ATCC 27980, DSM 43109, KCTC 9186, CCUG 37987, CIP 103451, IFO (now NBRC) 13917, JCM 3185, LMG 16326, NRRL B-5389, VKM Ac-805.

Sequence accession no. (16S rRNA gene): AF004988, X53211.

Additional remarks: the mycelium-forming strains mentioned in the literature under the species name *Nocardioides albus* compose a rather phylogenetically and chemotaxonomically heterogeneous group and some strains most likely will be described as novel species in future (see Further descriptive information for more information).

2. **Nocardioides aestuarii** Yi and Chun 2004b, 2152[VP]

a.es.tu.a'ri.i. L. gen. n. *aestuarii* of the tidal flat.

Characteristics are as described for the genus and listed in Table 215. Information presented below is taken from the original species description (Yi and Chun, 2004b).

Cells are nonmotile rods (ca. 0.3–0.4 × 0.9–2.1 μm) in 3-d-old culture on marine agar 2216 (MA; Difco). Colonies on MA are ivory, approximately 0.5–1 mm in the diameter after 3 d at 30°C, and reach the maximum diameter of 1–2 mm after 5 d. Substrate or aerial mycelium is not observed. Grows at 20–35°C, 0–8% (w/v) NaCl, and at initial pH 6–10; optimal growth was observed at 30°C, 0–2% (w/v) NaCl, and pH 7 as tested on ZoBell medium (Yi and Chun, 2004a; ZoBell, 1941) containing Bacto agar (Difco) 15 g, Bacto peptone (Difco) 5 g, yeast extract (Difco) 1 g, ferric citrate 0.1 g, sea salts 40 g, and 1 liter of distilled water (sea salts were not added when the relation to NaCl was tested). No growth occurs at 15 or 40°°C, at 9% (w/v) NaCl, and at pH 5 and 11 under the same experimental conditions. Utilizes acetate, L-lysine (weak), succinate, and other substrates (Table 215) in basal medium described by Baumann et al. (1972) supplemented with 2% (v/v) Hutner's mineral base (Cohen-Bazire et al., 1957) and modified by reducing the concentration of sea salts to half-strength. L-Arginine, L-asparagine, L-ornithine, D-sorbitol, and tartrate are not used as sole carbon sources on the same test medium. Acid was not produced from glucose using the API 20NE test system. Major fatty acids determined for the cells grown on MA at 30°C for 3 d were $C_{16:0}$ iso (52.0%), $C_{16:1}$ iso H (14.5%), $C_{17:1}$ ω8*c* (7.0%), $C_{17:0}$ 10-methyl (3.1%), and a small quantity (0.3%) of TBSA. The type strain (and the only strain described) was isolated using R2A agar (Difco) supplemented with artificial sea salts (Sigma) by the dilution plating method.

Source (type strain): sediment of tidal flat in Ganghwa Island, Korea (37°36′22.3 N, 126°22′59.4″ E).

DNA G+C content (mol%): 70 (HPLC).

Type strain: JC2056, IMSNU 14029, KCTC 9921, JCM 12125.

Sequence accession no. (16S rRNA gene): AY423719.

3. **Nocardioides agariphilus** Dastager, Lee, Ju, Park and Kim 2008f, 2295[VP]

a.ga.ri.phi′lus. N.L. n. *agarum* agar; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. masc. adj. *agariphilus* agar-loving.

Characteristics are as described for the genus and listed in Table 215. Information presented below is taken from the original species description (Dastager et al., 2008f).

Cells are irregular rods (0.4–0.5 × 1.3–3.0 µm) or cocci. Club-shaped and larger spherical forms reaching up to 2 µm in diameter occur in 7-d-old culture (28°C) on R2A agar. No aerial or substrate mycelium is formed. Motility is reported. Colonies on R2A agar are white to cream in color, and 1.5–2.7 mm in diameter after 7 d of incubation at 28°C. Will grow at 25–35°C, with optimum at 28°C; no growth occurs below 20°C or above 37°C. Optimum pH for growth is 7.5. Prefers a low salinity level; prefers not to grow in twofold-diluted R2A medium (Difco) in the presence of 2% (w/v) NaCl. The carbon sources for growth (according to Kämpfer, 1991) using mineral salts medium supplemented with yeast extract, Oxoid (0.02 g/l), bio-Lactysat, bioMérieux (0.02 g/l), a vitamin solution, and trace element solution (Kämpfer et al., 1990) are listed in Table 215. The organism was also reported to show growth on agar medium without any addition of carbon and nitrogen sources. Major fatty acids of cells harvested from twofold-diluted R2A broth (pH 7.5) after incubation for 10 d at 28°C were $C_{16:0}$ iso (37.6%), $C_{17:1}$ ω8*c* (9.8%), $C_{17:0}$ (7.1%), $C_{17:0}$ iso (5.8%), $C_{17:1}$ iso ω9*c* (5.1%), $C_{15:0}$ iso (4.9%), $C_{18:1}$ ω9c (4.3%), $C_{17:0}$ anteiso (3.9%), and $C_{17:0}$ 10-methyl (3.0%). Neither TBSA nor hydroxylated fatty acids were reported among components exceeding 2.4% of the total fatty acids. The type strain (and the only strain described) was isolated using a tenfold-diluted R2A medium (Difco).

Source (type strain): soil, Bigeum Island, Korea.

DNA G+C content (mol%): 69.4 (HPLC).

Type strain: MSL-28, DSM 19323, JCM 16020, KCTC 19276.

Sequence accession no. (16S rRNA gene): EF466113.

4. **Nocardioides alkalitolerans** Yoon, Kim, Lee, Lee and Oh 2005a, 813[VP]

al.ka.li.to′le.rans. Arabic article *al* the; Arabic n. *qaliy* ashes of saltwort; L. part. adj. *tolerans* tolerating; N.L. masc. part. adj. *alkalitolerans* referring to the ability to tolerate high pH.

Characteristics are as described for the genus and listed in Table 215, Table 216, and Table 217. Information presented below based on the original species description Yoon et al. (2005a), unless indicated.

Cells are rods (0.8–1.0 × 1.5–2.0 µm) in the exponential phase of growth and show rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. Neither substrate nor aerial mycelium is formed. Gram-stain-positive, but Gram staining is variable in old cultures. Colonies on twofold-diluted nutrient agar (NA; Difco) adjusted to pH 9.0 are milky-white in color and 0.7–1.0 mm in diameter after 7 d incubation at 30°C. Growth occurs at 4 and 34°C, but not at or above 35°C. Optimal pH for growth is 7.0–9.0, with the pH growth range of 5.5–12.0 [assessed in two-fold diluted nutrient broth, adjusted to alkaline pH with Na_2CO_3 (below pH 10.5) or KOH (above pH 10.5)]. Growth at pH 5.0 is variable, with no growth for type strain. Growth occurs at in up to 5% (w/v) NaCl (in trypticase soy broth). Nutritionally non-exacting; grows on a mineral salts medium (ISP 9) with glucose as carbon-plus-energy source and an ammonium salt as a sole nitrogen source. Adonitol and D-sorbitol are not utilized on the basal medium ISP 9; utilization of maltose varies among strains (the type strain is negative). Tweens 20, 40, and 60 are hydrolyzed; some strains, including the type strain, are able to hydrolyze gelatin. Some test results may vary between experiments (Dastager et al., 2010; Yoon et al., 2005a). The ability to oxidize some carbon substrates (Tóth et al., 2008) in the Biolog GP2 system are shown in Table 216. The major fatty acids determined for 4 strains grown on two-fold diluted NA agar (pH 9.0) at 30°C for 7 d, included TBSA (21.1–23.2%), $C_{16:0}$ iso (19.9–22.9%), $C_{18:1}$ ω9*c* (10.2–13.4%), $C_{17:1}$ ω6*c* (8.2–10.4%), $C_{16:0}$ (5.9–8.1%), $C_{18:0}$ (4.8–5.9%), and $C_{18:0}$ iso (4.0–5.2%). The DNA–DNA similarity levels between four strains of this species, including the type strain and strains KSL-9, KSL-10, and KSL-12) are 85–91%. The four characterized strains of this species were isolated using the dilution plating technique at 30°C on tenfold-diluted nutrient agar (NA; Difco) adjusted to pH 10.0 with Na_2CO_3.

Source (type strain): alkaline serpentinite soil, Korea.

DNA G+C content (mol%): 72.4–73.6 (HPLC); 71.7 for the type strain.

Type strain: KSL-1, KCTC 19037, DSM 16699, JCM 13365.

Sequence accession no. (16S rRNA gene): AY633969 for the type strain, and AY633970–AY633972 for strains KSL-9, KSL-10, and KSL-12.

5. **Nocardioides aquaticus** Lawson, Collins, Schumann, Tindall, Hirsch and Labrenz 2000b, 1953[VP] (Effective publication: Lawson, Collins, Schumann, Tindall, Hirsch and Labrenz 2000a, 226.)

a.qua′ti.cus. L. masc. adj. *aquaticus* living in water.

Characteristics are as described for the genus and listed in Table 215. Information presented below is based on the original species description (Lawson et al., 2000a), unless indicated.

Cells are predominantly coccoid (around 1.0 µm or more in diameter) or very short rods (0.9 × 1.0 µm), arranged in pairs or small clusters, as observable in 10–14 d cultures grown at 26°C on oligotrophic medium PYGV (DSM No. 621) (DSMZ, 2001; Staley, 1968) prepared with artificial sea water. Neither substrate nor aerial mycelium is formed. Colonies are mostly creamy or dull orange, and older cultures may be orange-colored. Grows at 16–26°C, in the presence of 1–6% NaCl (w/v) and at pH 7–8. The ranges of salinity and pH growth are 0–15% (w/v) NaCl and pH 5.5–9.5 (the maximal pH value examined); prefers not to grow at

3°C or 33.5°C. Growth occurs on marine agar (Difco) (Yi and Chun, 2004a) and is enhanced in the presence of thiamine and biotin (Lawson et al., 2000a). Acetate, pyruvate, glutamate, succinate, malate, and butyrate are utilized as carbon sources for growth in mineral salts medium supplemented with vitamins and traces of yeast extract (Labrenz et al., 1999). No growth with methanol as a carbon source. According to Yi and Chun (2004a), the type strain is able to grow with glucose, acetate, succinate, and other substrates as sole carbon sources on mineral salts medium (Baumann et al., 1971) supplemented with 2% (v/v) Hutner's mineral base (Cohen-Bazire et al., 1957) and modified by reducing the concentration of sea salts; does not utilize benzoate, tartrate, L-arginine L-asparagine, L-lysine, L-ornithine, sorbitol, and acetamide as sole carbon sources for growth. Weak (Lawson et al., 2000a) or no growth (Yi and Chun, 2004a) occurs with citrate. Tween 40 is hydrolyzed. NH_3 is produced from peptone. Methyl red test is negative. No acid is produced from glucose using the API 20NE strip (Yi and Chun, 2004a). More than 20 substrates are oxidized using the Biolog GP test system, including D-glucose, D-fructose, maltose, D-melibiose, D-psicose, L-rhamnose, stachyose, sucrose, D-trehalose, turanose, D-xylose, adonitol, glycerol, inositol, D-mannitol, acetate, succinamate, thymidine, and Tweens 40 and 80. Sensitive to chloramphenicol, penicillin G, and streptomycin as determined with bioDiscs (bioMérieux) after 4 d of growth. Peptidoglycan type is A3γ (LL-A_2pm-glycine). The cell-wall sugars are galactose and glucose. The major respiratory menaquinone is MK-8(H_4) (94% of the total), with MK-6(H_4) and MK-7(H_4) as minor components. The fatty acids analyzed according to Groth et al. (1996) in relatively young cells grown in trypticase soy broth (Difco) at 20°C included the following components: $C_{18:1}$ (30.6%), $C_{16:0}$ (14.1%), $C_{17:0}$ anteiso (10.6%), $C_{16:0}$ iso (8.1%), $C_{18:0}$ (6.9%), $C_{17:0}$ (5.9%), as well as TBSA (3.6%). The type strain (and the only strain characterized) was isolated using PYGV medium prepared with the natural water from Antarctic Ekho Lake, both for enrichment (15°C, 12 d) and subsequent isolation.

Source (type strain): water sample from Antarctic Ekho Lake (depth 1 m, salinity of 9.5%, temperature of 2.8°C, and pH of 8.04) located in the Vestfold Hills in East Antarctica.

DNA G+C content (mol%): 69 (HPLC).

Type strain: EL-17K, ATCC BAA-164, CIP 106993, DSM 11439, JCM 11266, NBRC 100371, NCIMB 703076 (formerly NCFB 3076).

Sequence accession no. (16S rRNA gene): X94145

6. **Nocardioides aquiterrae** Yoon, Kim, Kang, Oh and Park 2004, 74[VP]

a.qui.ter′ra.e. L. n. *aqua* water; L. gen. fem. n. *terrae* of earth or ground; N.L. gen. fem. n. *aquiterrae* pertaining to groundwater.

Characteristics are as described for the genus and listed in Table 215. Information presented below is based on the publications of Yoon et al. (2008, 2007a, 2004), unless indicated.

Cells are irregular rods (0.8–1.0 × 1.7–2.0 µm) in 7 d culture on nutrient agar (NA; Difco) at 30°C, forming small (0.5–1.0 mm in diameter) cream-colored colonies and show rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. Motile, a single lateral flagellum was observed. Neither substrate nor aerial mycelium is formed. Stained Gram-stain-positive or may be Gram-stain-variable in old cultures. Grows at 15 and 42°C (optimum, 30°C), but not at 10°C or temperatures above 43°C. Optimal pH for growth is 6.0–7.0; no growth occurs at pH 5.0. Nutritionally non-exacting; grows on a suitable mineral salts medium (ISP 9 medium) with glucose as the carbon-plus-energy source and an ammonium salt as the sole nitrogen source. Utilizes gentiobiose, turanose, gluconate, and malate as sole carbon and energy sources but not D-arabinose, D- and L-fucose, D-lyxose, D-tagatose, sorbose, stachyose, L-xylose, adonitol, L-arabitol, D-sorbitol, xylitol, glycogen, methyl β-D-xyloside, methyl α-D-mannoside, methyl α-D-glucoside, amygdalin, adipate, 2- and 5-ketogluconate, caprate, and phenylacetate. According to Yi and Chun (2004a), the type strain also uses acetate, succinate, tartrate (weak), acetamide, L-asparagine, and L-lysine as carbon sources for growth and energy, but not benzoate, L-arginine, and L-ornithine. Tributylin is hydrolyzed (Song et al., 2011). Utilization of citrate, lactose, L-rhamnose, D-ribose, and esculin, hydrolysis of Tween 80 and starch, activities for β-galactosidase and trypsin may vary with experiments or the test method (Song et al., 2011; Yi and Chun, 2004a; Yoon et al., 2008; Yoon et al., 2004). Acid not produced from glucose using the API 20NE test system (Yi and Chun, 2004a). Sensitive to chloramphenicol (100 µg), streptomycin (50 µg) and ampicillin (10 µg), but tolerates tetracycline (30 µg) and rifampin (30 µg), as assessed using filter-paper discs (Song et al., 2011).

The fatty acids of cells harvested from NA after 6 d incubation at 30°C included (>4%): $C_{16:0}$ iso (57.6%), $C_{17:0}$ anteiso (9.0%), $C_{16:1}$ iso H (6.8%), $C_{15:0}$ iso (4.9%), and $C_{17:0}$ 10-methyl (4.1%) as well as TBSA (0.8%). The fatty acids determined for cells grown on half-strength R2A agar plates for 3 d at 30°C (Song et al., 2011) were a smaller proportion of $C_{16:0}$ iso (29.9%) and larger proportions of straight-chain unsaturated (>15%) and saturated (7.7%) acids. Song et al. (2011) compared the fatty acid profiles of *Nocardioides aquiterrae* and phylogenetically related species (*Nocardioides pyridinolyticus*, *Nocardioides hankookensis*, and *Nocardioides caricicola*). The levels of DNA–DNA hybridization between the type strains of *Nocardioides aquiterrae* and the phylogenetically closest species *Nocardioides pyridinolyticus* (99.2% 16S rRNA gene similarity) were 32.5 and 28.7% in reciprocal experiments using the procedure of Ezaki et al. (1989). A lower DNA similarity value (19%) was determined with respect to *Nocardioides hankookensis* (98.1% 16S rRNA gene sequence similarity) (Yoon et al., 2008). The following characteristics are helpful in distinguishing *Nocardioides aquiterrae* from the above-mentioned close species: the cell size and motility, optimal and maximal growth temperatures, activity for cytochrome oxidase, nitrate reduction, alkaline phosphatase, esterase (C4) and α-glucosidase, utilization of D-melezitose, D-melibiose, gentiobiose, D-ribose, D-arabitol, and inositol, as well as sensitivity to antibiotics (ampicillin, chloramphenicol, streptomycin, rifampin, and tetracycline; Song et al., 2011; Yoon et al., 2004, 2008). The type strain (and the only strain described) was isolated by the dilution plating technique using NA at 30°C.

Source (type strain): groundwater, Korea.
DNA G+C content (mol%): 73 (HPLC).
Type strain: GW-9, KCCM 41647, JCM 11813.
Sequence accession no. (16S rRNA gene): AF529063.

7. **Nocardioides aromaticivorans** Kubota, Kawahara, Sekiya, Uchida, Hattori, Futamata and Hiraishi 2005b, 984[VP] (Effective publication: Kubota, Kawahara, Sekiya, Uchida, Hattori, Futamata and Hiraishi 2005a, 172.)

a.ro.ma.ti.ci.vo′rans. L. adj. *aromaticus* aromatic, fragrant; L. part. adj. *vorans* devouring; N.L. part. adj. *aromaticivorans* devouring aromatic (compounds).

Characteristics are as described for the genus and listed in Table 215, Table 218, Table 219, and Table 221. Information presented below is based on the original species description (Kubota et al., 2005a), unless indicated.

Cells are nonmotile rods (0.5–0.7 × 1.0–2.0 µm). Transmission electron microscopy with negatively stained cells demonstrated the presence of septa in the middle of some rods, which suggests that coccoid cells may occur in old cultures on some media. Neither substrate nor aerial mycelium is formed. Colonies are milky-white on complex agar media, e.g. on a peptone-beef extract–yeast extract agar medium (Futamata et al., 2004). Growth occurs in the temperature range of 22–40°C (optimum, 30°C) and pH range 5–8 (optimum, pH 7). Dibenzofuran, biphenyl, and dibenzo-*p*-dioxin (weak) are utilized as sole carbon and energy sources, with formation of yellow-orange pigments. Cui et al. (2009) reported the ability of the type strain to utilize *p*-nitrophenol. Cellobiose, maltose, D-mannose, sucrose, trehalose, and D-mannitol are utilized as carbon and energy sources (API CH50), but growth may be weak with these sugars. The carbon sources not utilized include D-arabinose, L-sorbose, L-xylose, fucose, D-tagatose, adonitol, arabitol, dulcitol, erythritol, sorbitol, xylitol, gluconate, 2- and 5-ketogluconate, glycogen, amygdalin, α-methyl-D-glucoside, and α-methyl-D-mannoside (API CH50). Yoon et al. (2009) additionally reported positive reaction of the type strain in the tests for utilization of D- and L-fucose, D- and L-arabitol, adipate and malate, as well as negative results in the tests for utilization of gentiobiose, arbutin, esculin, starch, caprate, and phenylacetate (API 50 CH, API 20NE). Weak or no growth is observable with D-lyxose (Kubota et al., 2005a; Yoon et al., 2009). The type strain grows with L-alanine, L-histidine, L-proline, L-serine, acetate, caprate, 2-ketogluconate, malic acid, propionic acid, suberic acid, and valeric acid as sole carbon and energy sources (conventional tests with mineral salts medium supplemented with vitamins and element solution) but not with adipate, citrate, itaconate, 3- and 4-hydroxybenzoic acids, 3-hydroxybutyrare, 5-ketogluconate, lactate, malonate under the same test conditions (Cui et al., 2009). Production of acetoin was reported (Cui et al., 2009). The major cellular fatty acids determined using the method of Suzuki and Komagata (1983a, 1983c) for seven strains grown at 25°C in a complex liquid medium included $C_{16:0}$ iso (32.8–49.0%), $C_{18:1}$ (11.8–22.1%), $C_{17:0}$ iso (11.9–13.5%), $C_{18:0}$ iso (4.9–7.0%), $C_{17:1}$ (3.0–5.6%), $C_{19:0}$ iso (2.6–3.7%), $C_{17:0}$ (2.0–5.0%), and $C_{17:0}$ anteiso (2.4–4.2%). Neither 10-methyl-branched nor hydroxylated fatty acids were detected. In contrast, the cells harvested from trypticase soy agar (Difco) after incubation at 30°C for 2 d produced $C_{17:0}$ 10-methyl and TBSA, as well as $C_{15:0}$ 3-OH acid (Cui et al., 2009) as shown in Table 219 (also contains data on fatty acids of the type strains of the phylogenetically closest species). The levels of DNA–DNA hybridization between seven strains (H-1, H-2, A-1, A-2, A-3, NSA1-1, and NSA1-2) assigned to *Nocardioides aromaticivorans* exceed 78%. The two strains (H-1 and NSA1-2) affiliated with this species showed DNA–DNA hybridization levels of 17–55% with the type strains of the phylogenetically closest *Nocardioides* species Table 221. The DNA–DNA hybridization values for type strains of more distant species obtained by the method of Ezaki et al. (1989) were 25–29% (*Nocardioides plantarum*) to 32–40% (*Nocardioides albus*, *Nocardioides luteus*, and *Nocardioides jensenii*). Selected phenotypic characteristics differentiating *Nocardioides aromaticivorans* from the phylogenetically closest species are listed in Table 218. Occur in various environments (river water, river sediments, and soil) polluted with polychlorinated dibenzo-*p*-dioxins and dibenzofurans. A dibenzofuran-containing mineral salts medium supplemented with a vitamin solution can be used for enrichment and subsequent isolation. Colonies showing soluble yellow pigment production on the dibenzofuran-containing agar are picked up and subjected to the standard purification procedure, culture on a suitable medium, and strain identification. For details on the enrichment and

TABLE 221. Mean levels of DNA–DNA hybridization (%) between the type strains of *Nocardioides simplex* and closely related species[a,b]

Species	*N. simplex*	*N. aromaticivorans*	*N. nitrophenolicus*	*N. kongjuensis*
1. *N. aromaticivorans*	48–55			
2. *N. nitrophenolicus*	41	48–49		
3. *N. kongjuensis*	21–28	22–36	38–46	
4. *N. ginsengisoli*[c]	33	28	25	22
5. *N. caeni*	13	17	22	31

[a]Data from Yoon et al. (1999, 2006b, 2009), Kubota et al. (2005a), Kim et al. (2009b) and Cui et al. (2009) obtained by the method of Ezaki et al. (1989).

[b]There are no data on the DNA–DNA hybridization level between *Nocardioides ginsengisoli* and *Nocardioides caeni*. These species were described independently by different research groups almost simultaneously (Cui et al., 2009; Yoon et al., 2009).

[c]Close binding values (18–36%) in the reciprocal experiments were obtained for the four species (*Nocardioides aromaticivorans*, *Nocardioides kongjuensis*, *Nocardioides nitrophenolicus*, and *Nocardioides simplex*).

the isolation procedure, see Futamata et al. (2004), Hiraishi and Kitamura (1984), and Kubota et al. (2005b).

Source (type strain): water from the Hikichi river polluted with polychlorinated dibenzo-*p*-dioxins and dibenzofurans, Kanagawa, Japan.

DNA G+C content (mol%): 72.0–72.4 (HPLC).

Type strain: H-1, CIP 108782, DSM 15131, IAM 14992, JCM 11674.

Sequence accession no. (16S rRNA gene; type strain): AB087721.

8. **Nocardioides basaltis** Kim, Roh, Chang, Nam, Yoon, Jeon, Oh and Bae 2009a, 46[VP]

ba.sal′tis. L. gen. n. *basaltis* of basalt, pertaining to the composition of sand, a source of isolation.

Characteristics are as described for the genus and listed in Table 215. Characteristics presented below are taken from the original species description (Kim et al., 2009a).

Cells are nonmotile rods (0.7–1.0 × 1.2–2.0 µm), forming creamy-colored colonies (0.5–1.5 mm in diameter) after 3 d growth on marine agar (MA; Difco) at 30°C. Grows at 10–37°C (optimum about 25–30°C) but not at 4 or 41°C. Grows in marine broth at initial pH 5.5–8.0 (optimally at pH 6–7). Salt-dependent; grows in marine broth containing 1–10% (w/v) NaCl (optimally at 1–2% NaCl), but not in the absence of NaCl. No growth also occurs on the standard R2A agar (Difco) or tripticase soy agar (TSA; Difco). Positive for assimilation of D-arabitol, gluconate and turanose according to the API 50 CH test system examined using inoculation medium AUX supplemented with 1.5% (w/v) NaCl. Negative for assimilation of D-adonitol, amygdalin, D-arabinose, L-arabitol, arbutin, dulcitol, erythritol, D-fucose, L-fucose, gentiobiose, glycogen, inulin, 2- and 5-ketogluconate, D-lyxose, methyl α-D-glucopyranoside, methyl α-D-mannopyranoside, methyl D-xylose, D-sorbitol, L-sorbose, D-tagatose, L-xylose, and xylitol under the same test conditions. No acid is produced from glucose using the API 20NE test system. Fatty acids (>2%) determined for cells grown on MA at 30°C for 3 d included $C_{16:0}$ iso as the predominant component (70.3%), along with $C_{17:1}$ ω8*c* (4.3%), $C_{16:1}$ iso H (3.7%), $C_{14:0}$ iso (3.5%), $C_{17:0}$ 10-methyl (3.2%), $C_{18:1}$ ω9*c* (2.8%), and $C_{18:0}$ iso (2.7%). No TBSA was revealed among fatty acids exceeding 1%. Generally similar profile, with $C_{16:0}$ iso predominating (65.3%), was reported for the phylogenetically closest species, *Nocardioides salarius*, obtained for a younger (1 d) culture grown under the same conditions (Kim et al., 2008a). The fatty acid profile of another phylogenetically close species, *Nocardioides marinisabuli*, grown for 3 d and analyzed under the same experimental conditions as *Nocardioides basaltis*, differed from the latter in that it contained a smaller proportion of $C_{16:0}$ iso (35.9%), and larger proportions of $C_{18:1}$ ω9*c* (15.4%) and $C_{17:0}$ iso (12.3%). The DNA–DNA relatedness between the type strains of this species and phylogenetically very close species *Nocardioides marinisabuli* (99.2% 16S rRNA similarity) was 15.8±1.5%. Mean DNA–DNA similarities with the type strains of more distant species, *Nocardioides terrigena* and *Nocardioides kribbensis*, were 7.0 and 28.7%, respectively. There are no available data on DNA–DNA relatedness to the phylogenetically closest species, *Nocardioides salarius* (Kim et al., 2008a). Sharing many phenotypic features in common with *Nocardioides salarius*, including the fatty acid profile and physiological and biochemical traits (Table 215), the type strain of *Nocardioides basaltis* still appears to differ from that of *Nocardioides salarius* by absence of acid phosphatase, α-chymotrypsin, and valine arylamidase (API ZYM), inability to decompose esculin, Tween 80, and tyrosine, ability to use salicin as a carbon source, having larger-sized cells, and a lower DNA G+C content. The type strain (and the only strain described) was isolated by the dilution plating technique using NA at 30°C.

Source (type strain): black sand, beach, Soesoggak, Jeju Island, Korea.

DNA G+C content (mol%): 68 (T_m).

Type strain: J112, JCM 14945, KCTC 19365.

Sequence accession no. (16S rRNA gene): EU143365.

Additional remarks: the species *Nocardioides basaltis* Kim et al. 2009a described shortly after the establishment of the species *Nocardioides salarius* Kim et al. 2008a has very similar 16S rRNA gene sequence similarity (99.6%) to *Nocardioides salarius*, while the data on the DNA–DNA relatedness between these species are absent. Further comparative taxonomic studies of these two species seem to be needed to justify the separate species status of *Nocardioides basaltis*.

9. **Nocardioides bigeumensis** Dastager, Lee, Ju, Park and Kim 2008f, 2295[VP]

bi.ge.um.en′sis. N.L. masc. adj. *bigeumensis* of or pertaining to Bigeum Island, Korea, the geographical origin of the type strain.

Characteristics are as described for the genus and listed in Table 215. Information presented below based on the original species description (Dastager et al., 2008f).

Cells are cocci or irregular rods (0.3–0.8 × 0.8–4.0 µm). Larger spherical forms, up to 1.5 µm in diameter are reported. Motile. Colonies are cream in color, flat and 1.0–2.5 mm in diameter after 4–5 d incubation on R2A at 28°C. No aerial or substrate mycelium is produced. Grows at 20–35°C (optimum 28°C) and at pH 7.5–9.0. Prefers low salinity; no growth is observed in twofold-diluted R2A in the presence of 1% (w/v) NaCl or more. The carbon sources for growth (Kämpfer, 1991) using mineral salts medium supplemented with yeast extract, Oxoid (0.02 g/l), bio-Lactysat, bioMérieux (0.02 g/l), a vitamin solution, and trace element solution (Kämpfer et al., 1990) are listed in Table 215. The major fatty acids determined in cell mass harvested from twofold-diluted R2A broth (pH 7.5) after incubation for 10 d at 28°C were reported to include $C_{16:0}$ iso (38.3), $C_{15:0}$ iso (13.1), $C_{14:0}$ iso (9.0), $C_{18:1}$ ω9*c* (6.3), $C_{16:0}$ 10-methyl (4.8), $C_{16:0}$ (4.4), and $C_{17:1}$ ω8*c* (3.9). Neither TBSA nor hydroxylated fatty acids exceeded 1%. The type strain (and the only strain described) was isolated using a tenfold-diluted R2A medium by the standard dilution plating method.

Source (type strain): soil, Bigeum Island, Korea.

DNA G+C content (mol%): 69.3 (HPLC).

Type strain: MSL-19, DSM 19320, JCM 16021, KCTC 19290.

Sequence accession no. (16S rRNA gene): EF466114.

10. **Nocardioides caeni** Yoon, Kang, Park, Kim and Oh 2009, 2796[VP]

ca.e′ni. L. gen. n. *caeni* of sludge, isolated from wastewater.

Characteristics are as described for the genus and listed in Table 215, Table 218, Table 219, and Table 221. Information presented below is taken from the original species description (Yoon et al., 2009), unless indicated.

Cells are nonmotile rods or cocci (0.3–0.7 × 0.7–2.5 µm) and can undergo a rod-to-coccus morphogenetic cycle from the early exponential phase to the stationary phase. Gram-stain-positive but results of Gram-staining vary in old cultures. Colonies on nutrient agar (NA; Difco) are grayish yellow and 1.5–2.5 mm in diameter after incubation for 7 d at 30°C. Neither substrate nor aerial mycelium is formed. Optimal temperature for growth is 30°C. The organism grows at 10 and 35°C, but not at 4 or 37°C. Growth occurs in the presence of 0–1.0% (w/v) NaCl, with optimum growth at 0–0.5% (w/v) NaCl and no growth at 2% (w/v) NaCl (assessed in trypticase soy broth prepared according to the formula of the Difco medium without NaCl). Optimal pH for growth is 6.5–7.5; growth occurs at pH 6.0 and 9.5, but not at pH 5.5 or 10.0 [initial pH of the test medium, nutrient broth (NB; Difco) adjusted to various pH by adding HCl or Na_2CO_3]. Positive for assimilation of gluconate, adipate, and malate, but negative for assimilation of 2- and 5-ketogluconate, caprate, and phenylacetate (API 20NE), as well as D-arabinose, sorbose, adonitol, D- and L-arabitol, dulcitol, erythritol, sorbitol, xylitol, methyl α-D-mannoside, methyl α-D-glucoside, amygdalin, arbutin, glycogen, gentiobiose, D-tagatose, D-fucose, and L-fucose (API 50 CH, AUX as suspending medium). Tweens 20, 40, and 60 are hydrolyzed. Susceptible to the following antibiotics (amounts per disc): carbenicillin (100 µg), cephalothin (30 µg), chloramphenicol (100 µg), gentamicin (30 µg), kanamycin (30 µg), neomycin (30 µg), novobiocin (5 µg), oleandomycin (15 µg), penicillin G (20 U), polymyxin B (100 U), streptomycin (50 µg), and tetracycline (30 µg). Resistant to the following antibiotics (amounts per disc): ampicillin (10 µg) and lincomycin (15 µg). Major fatty acids (>5.0% of the total) determined in cell mass harvested from NA plates after incubation for 7 d at 30°C included $C_{16:0}$ iso, $C_{18:1}$ ω9*c*, $C_{17:1}$ ω8*c*, $C_{17:1}$ ω6*c*, and $C_{17:0}$ iso (Table 219); no TBSA was not detected among fatty acids exceeding 0.5%. The type strain exhibited the DNA–DNA similarity values of 13–31% to type strains of the most closely related species (Table 221). Selected phenotypic characteristics differentiating *Nocardioides caeni* from phylogenetically closely related species are listed in Table 218. The type strain (and the only strain described) was isolated by means of the standard dilution plating technique on NA at 30°C.

Source (type strain): sludge of domestic wastewater, Korea.

DNA G+C content (mol%): 71.5 (HPLC).

Type strain: MN8, KCTC 19600, CCUG 57506.

Sequence accession no. (16S rRNA gene): FJ423551.

11. **Nocardioides caricicola** Song, Yasir, Bibi, Chung, Jeon and Chung 2011, 108[VP]

ca.ri.ci′co.la. L. n. *carex -icis* reed-grass, rush or sedge, and also a botanical genus name (*Carex*); L. suff. *-cola* (from L. n. *incola*), inhabitant, dweller; N.L. n. *caricicola*, *Carex*-dweller, isolated from a halophytic plant *Carex scabrifolia* Steud.

Characteristics are as described for the genus and listed in Table 215. Information presented below is taken from the original species description (Song et al., 2011).

Cells are irregular rods (0.4–0.6 × 2.0–5.0 µm) to cocci (Figure 256) in 5-d-old culture grown in half-strength R2A broth (Difco). No flagella were observed for cells grown in the same medium for 2 d at 30°C. Colonies are convex, glistening, white in color and 0.5–0.7 mm in diameter after 5 d of incubation at 30°C on half-strength R2A agar (1.6 g R2A broth powder supplemented with 1.5% agar in 1 L of distilled water). The organism grows in half-strength R2A broth with 0.5% (w/v) NaCl and on marine agar 2216 (MA, Difco). No growth is observable in half-strength R2A broth supplemented with 1% (w/v) NaCl. The pH range for growth reported is also narrow, 7.0–9.0 (optimum pH 8.0); no growth at pH 6.5 and 9.5 (assessed on half-strength R2A agar). Grows at 10 and 45°C, where the latter is the maximal growth temperature reported for the recognized *Nocardioides* species, and not at 50°C (half-strength R2A agar plates). Acid is produced from D-glucose (API 20E). No assimilation of any carbon source was observed using API 20NE test system (no inoculation medium is reported). Tween 20 is decomposed. Tributylin or xylan is not decomposed. Nitrate is reduced to nitrogen gas. Susceptible to the following antibiotics (µg per filter-paper disc): chloramphenicol (100), gentamicin (10), kanamycin (30), penicillin (10), rifampin (30), streptomycin (50), and vancomycin (30); resistant to ampicillin (10) and tetracycline (30). The major cellular fatty acids (>5.0%) determined for cells harvested from half-strength R2A agar plates after incubation for 3 d at 30°C comprised $C_{16:0}$ iso (28.9%), $C_{18:1}$ ω5*c* (7.0%), and $C_{14:0}$ (6.6%), as well as $C_{18:2}$ ω6*c*, $C_{18:2}$ ω9*c*, and/or $C_{18:0}$ anteiso (8.1%). Minor contents of TBSA (1.7%) and $C_{17:0}$ 10-methyl (3.3%) were also detected. Song et al. (2011) compared the fatty acid profiles of the type strains of *Nocardioides caricicola* and related species (*Nocardioides aquiterrae*, *Nocardioides hankookensis*, and *Nocardioides pyridinolyticus*) obtained under the same experimental conditions. DNA–DNA relatedness between the type strains of this species and *Nocardioides pyridinolyticus* was determined to be 53.5 ± 5.5%. The type strain (and the only strain described) was isolated from the surface-sterilized plant roots. Following sterilization (70% ethanol, 1.0% NaOCl and again 70% ethanol), washing and checking for the surface sterility, a root sample was dried, grounded in sterile sea water and plated on 1/10-strength R2A agar, followed by incubation at 25°C for 1–2 weeks (for details on the isolation procedure see Chung et al., 2008; Song et al., 2011).

Source (type strain): roots of a halophytic plant, *Carex scabrifolia* Steud, growing on sand dunes, Namhae Island, Korea.

DNA G+C content (mol%): 71.7 (HPLC).

Type strain: YC6903, KACC 13778, DSM 22177.

Sequence accession no. (16S rRNA gene): FJ750845.

12. **Nocardioides daedukensis** Yoon, Park, Kang, Lee, Lee and Oh 2010, 1337[VP]

da.e.duk.en′sis. N.L. masc. adj. *daedukensis* of or pertaining to Daeduk Science Park, where the Korea Research Institute of Bioscience and Biotechnology is located.

Characteristics are as described for the genus and listed in Table 215 and Table 216. Information presented below is taken from the original species description (Yoon et al., 2010).

Cells are nonmotile irregular rods or cocci (0.4–0.8 × 0.8–3.0 μm) and show rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. Gram-stain-positive but Gram-staining is variable in old cultures. Colonies on nutrient agar (NA; Difco) are pale yellow in color, glistening, raised, and 1.0–1.5 mm in diameter after incubation for 7 d at 30°C. Neither substrate nor aerial mycelium is formed. Grows at 4 and 37°C (optimally at 30°C), but not at 40°C. Growth is observable at pH 6.0 and 10.0 (optimum at pH 7.0–8.0), but not at pH 5.5 and 10.5, as assessed in nutrient broth (NB; Difco) adjusted to different pH values with HCl or Na_2CO_3. Tolerates salinity up to 9.0% (w/v) NaCl (tested in trypticase soy broth prepared according to the Difco formula, with a definite NaCl concentration), however prefers low NaCl concentrations for growth, 0–0.5% (w/v). Nutritionally non-exacting; grows on a mineral salts medium (ISP 9 medium) with glucose as carbon-plus-energy source and an ammonium salt as sole nitrogen source. Glutamate, acetate, L-malate and pyruvate are utilized as a sole carbon and energy sources on the same basal medium, while negative test results are observable for benzoate, citrate, formate, and succinate. Tweens 20, 40, and 60 are hydrolyzed. Susceptible to the following antibiotics (amounts per disc): carbenicillin (100 μg), cephalothin (30 μg), chloramphenicol (100 μg), gentamicin (30 μg), kanamycin (30 μg), lincomycin (15 μg), neomycin (30 μg), oleandomycin (15 μg), penicillin G (20 U), polymyxin B (100 U), streptomycin (50 μg), and tetracycline (30 μg). Resistant to ampicillin (10 μg) and novobiocin (5 μg).The major fatty acids determined for cells harvested from NA plates after cultivation for 7 d at 30°C were $C_{16:0}$ iso (40.9%), $C_{17:1}$ (15.5%), $C_{17:0}$ 10-methyl (12.2%), $C_{18:1}$ (7.6%), TBSA (6.3%), and $C_{16:1}$ iso (3.5%), as well as minor amounts of other acids, including $C_{17:0}$ 3-OH (1.2%). The fatty acid profile differed from that of the type strain of phylogenetically close *Nocardioides jensenii* and *Nocardioides dubius* (analyzed under the same experimental conditions). In particular, *Nocardioides jensenii* contained a greater proportion of $C_{16:1}$ iso (10.9%), whereas *Nocardioides dubius* had a smaller proportion of $C_{17:1}$ (1.4%) and a significantly larger total iso-branched acids. The major polar lipids of cells grown in NB for 7 d at 30°C are diphosphatidylglycerol, an unidentified phospholipid, and two unidentified lipids. Minor components detected included phosphatidylglycerol, phosphatidylethanolamine, and an unidentified phospholipid. The organism did not contain a compound identical to phosphatidylinositol that was reported for *Nocardioides jensenii* (Collins et al., 1989), *Nocardioides dubius* (Yoon et al., 2005d), and *Marmoricola aurantiacus* (Urzì et al., 2000).

The type strain exhibited mean DNA–DNA relatedness values of 19% to the type strain of the phylogenetically closest species, *Nocardioides jensenii* (98.3% 16S rRNA similarity) and of 10% to *Nocardioides dubius.* The type strain (and the only strain described) was isolated by the standard dilution plating technique on ten-diluted NA at 30°C.

Source (type strain): soil at Taejon, South Korea.

DNA G+C content (mol%): 68.7 (HPLC).

Type strain: MDN22, KCTC 19601, CCUG 57505.

Sequence accession no. (16S rRNA gene): FJ842646.

13. **Nocardioides daphniae** Tóth, Kéki, Homonnay, Borsodi, Márialigeti and Schumann 2008, 81[VP]

daph.ni′a.e. N.L. gen. n. *daphniae* of *Daphnia*, generic name of water flea (*Daphnia cucullata*) from which the type strain was isolated.

Characteristics are as described for the genus and listed in Table 215, Table 216, and Table 217. Information presented below is based on the original description (Tóth et al., 2008), unless indicated.

Cells are short rods or coccoids (0.8–1.0 × 1.2–2.2 μm). Nonmotile. Colonies on King B agar medium (King et al., 1954) are of yellowish color. Neither substrate nor aerial mycelium is produced.

The organism grows at 4–38°C, at initial pH values of 5.5–10.5, and at NaCl concentrations up to 5% (w/v), with optimum growth at 28°C and pH 7–9; no growth occurs at 45°C, at pH 11, and in the presence of 10% (w/v) NaCl (King B agar or broth as basal media). Good growth also occurs on standard nutrient agar (NA, Difco) and trypticase soy agar. The organism grows on mineral salts medium (ISP 9) with glucose and other substrates (Table 215) as carbon-plus-energy sources and an ammonium salt as a sole nitrogen source (Dastager et al., 2010). Produces chitinase (tested using a modified version of the method of Holding and Collee, 1971). No acid produced from glucose in the O/F test (Hugh and Leifson, 1953). Hemolysin is not detected. Data on the oxidation of carbon substrates assessed with the Biolog GP2 test system are listed in Table 216. In addition, the type strain oxidizes methyl-β-D-glucoside, sorbitol, stachyose, acetic acid, β-hydroxybutyric acid, γ-hydroxybutyric acid, α-ketovaleric acid, L-lactic acid, D-malic acid, methyl-pyruvate, glycyl L-glutamic acid, pyruvic acid, 2,3-butanediol, adenosine, 2-deoxyadenosine, thymidine, uridine, adenosine 5′-monophosphate, and uridine 5′-monophosphate but not the remaining Biolog GP2 substrates (about 50 substrates). The major fatty acids determined for cells grown on trypticase soy agar (Difco) at 28°C included $C_{16:0}$ iso (42.7%), $C_{18:1}$ ω9*c* (9.9%), $C_{17:0}$ 10-methyl (9.7%), $C_{17:0}$ iso (8.2%), and $C_{17:1}$ iso ω9*c* (8.1%). Components detected in smaller proportions were $C_{17:1}$ ω8*c* (3.6), $C_{16:1}$ iso (2.6), $C_{17:0}$ anteiso (2.4), $C_{18:0}$ iso (2.4), $C_{16:1}$ ω7*c* (2.2), and some others typical of the genus. The type strain (and the only strain described) was isolated using King B agar medium (King et al., 1954).

Source (type strain): whole-body homogenate sample of *Daphnia cucullata* (Crustacea: Cladocera) adult individuals, Lake Balaton at Tihany (46°55′20″N; 17°55′39″E), Hungary.

DNA G+C content (mol%): 69.9 (HPLC).

Type strain: D287, DSM 18664, CCM 7403, JCM 16608.

Sequence accession no. (16S rRNA gene): AM398438.

14. **Nocardioides dilutus** Dastager, Lee, Ju, Park and Kim 2009b, 1555[VP] (Effective publication: Dastager, Lee, Ju, Park and Kim 2008d, 572.)

di.lu′tus. L. masc. adj. *dilutus* weak, diluted, intended to mean that the organism is able to grow in 100 times diluted R2A medium.

Characteristics are as described for the genus and listed in Table 215 and Table 216. Information presented below is taken from Dastager et al. (2008d, 2010).

Cells are irregular rods (0.4–0.8 µm in diameter; up to 4.0 µm in length) or cocci. The 5-d-old culture grown on R2A agar (Difco) at 28°C is composed of shorter cells (mostly 0.4–0.6 × 0.8–1.6 µm) with a small proportion of coccoid cells. Motile. Colonies on R2A are irregular, smooth, flat, and white to cream in color; 1.5–2.7 mm in diameter after 5 d incubation at 28°C. Neither substrate nor aerial mycelium is formed. Nutritionally non-exacting; grows on a mineral salts medium (e.g. ISP 9) with glucose and other substrates as carbon-plus-energy sources and an ammonium salt as a sole nitrogen source. Growth occurs on solid media with low nutrient concentrations, including 100-fold diluted R2A. Prefers not to grow in R2A broth supplemented with 1% (w/v) NaCl or more. Cell-wall peptidoglycan contains A_2pm as the diagnostic diamino acid (no A_2pm isomer is reported). Fatty acids determined in cell mass harvested from R2A broth after incubation for 7 d at 28°C included (% of the total): $C_{16:0}$ iso (46.7%), $C_{18:1}$ ω9*c* (12.4%), $C_{17:1}$ ω8*c* (5.5%), $C_{14:0}$ iso (4.3%), $C_{17:0}$ anteiso (4.2%), $C_{16:0}$ (3.8%), $C_{17:0}$ (2.9%), $C_{18:0}$ (2.7%), $C_{15:0}$ anteiso (2.5%), $C_{15:0}$ iso (2.4%), $C_{16:1}$ iso (2.0%), and $C_{17:0}$ (1.2%). The type strain (and the only strain described) was isolated by serial dilution plating on tenfold-diluted R2A agar at 30°C after 7 d incubation.

Source (type strain): soil, Bigeum Island, Korea.

DNA G+C content (mol%): 71.8 (HPLC).

Type strain: MSL-11, KCTC 19288, DSM 19318.

Sequence accession no. (16S rRNA gene): EF466121.

15. **Nocardioides dokdonensis** Park, Baik, Kim, Chun and Seong 2008, 2622[VP]

dok.do.nen′sis. N.L. masc. adj. *dokdonensis* of or pertaining to Dokdo, the Korean island from where the type strain was isolated.

Characteristics are as described for the genus and listed in Table 215. Information presented below based on the original description (Park et al., 2008).

Cells are relatively short rods (0.6–0.9 × 1.2–1.8 µm) in the exponential phase of growth. Nonmotile. Colonies on trypticase soy agar (TSA; Difco) are cream in color and approximately 1.0–2.0 mm in diameter after 3 d at 25°C, reaching a maximum diameter of 3 mm after 7 d. Substrate and aerial mycelia are not observed. Grows at 4–30°C (optimum, 25°C), at pH 5–10 (optimum, pH 7), and in up to 7% (w/v) NaCl, with the optimum growth in 0–3% (w/v) NaCl, as assessed on TSA. The following substrates are utilized as sole carbon and energy sources for growth: adonitol, sodium acetate, sodium citrate, sodium propionate, sodium pyruvate, and other carbon sources (Table 215) as tested on Stevenson's basal medium (Stevenson, 1967).* Acetate, adipate, caprate, phenyl acetate, malate, gentiobiose, dextran, DL-xylitol are not utilized on the same basal medium. The following substrates are utilized as sole nitrogen sources: L-cysteine, L-hydroxyproline, L-phenylalanine, L-threonine, L-valine, and nitrate, but not DL-α-amino-*n*-butyric acid or L-histidine (examined using Tsukamura's medium; Tsukamura, 1975). Allantoin, guanine, Tween 20, and xylan are hydrolyzed, but arbutin, elastin, and hippurate are not. Acids are not produced from D-glucose and maltose using the API 20 NE system. In the Biolog GP2 system, the type strain oxidizes 29 of 97 substrates including acetate, adenosine, adenosine 5′-monophosphate, β-cyclodextrin, 2′-deoxyadenosine, D-fructose, glycerol, β-hydroxybutyric acid, γ-hydroxybutyric acid, inosine, α-ketovaleric acid, maltotriose, D-mannitol, D-mannose, melezitose, melibiose, propionic acid, D-psicose, pyruvic acid, D-ribose, sedoheptulosan, D-sorbitol, succinic acid, thymidine, trehalose, Tween 40, Tween 80, uridine, and D-xylose. The type strain is sensitive to the following antibiotics (µg per disc, unless indicated): amikacin (30), ampicillin (10), chloramphenicol (30), erythromycin (15), gentamicin (10), kanamycin (30), nalidixic acid (30), streptomycin (10), tetracycline (30), vancomycin (30), penicillin (10 U), and polymyxin B (300 U). The major cellular fatty acids determined for the type strain grown on TSA for 2 d at 25°C were $C_{16:0}$ iso (40.4%), $C_{18:1}$ ω9*c* (11.2%), $C_{16:0}$ (7.7%), $C_{18:0}$ (7.2%), $C_{17:0}$ iso (4.8%), and $C_{17:1}$ ω8*c* (4.6%). TBSA was not detected; the only 10-methyl-branched acid, i.e. $C_{17:0}$ 10-methyl contributed 1.4%. The DNA–DNA similarity between the type strains of *Nocardioides dokdonensis* and *Nocardioides marinisabuli* was 23.1±5.6%. The type strain (and the only strain described) was isolated by the standard dilution plating technique using R2A agar (Difco) supplemented with 3.5% artificial sea salts (Sigma).

Source (type strain): sand sediment, a beach on Dokdo Island, Korea (37°05′N; 131°13′E).

DNA G+C content (mol%): 69.1 (HPLC).

Type strain: FR1436, KCTC 19309, JCM 14815.

Sequence accession no. (16S rRNA gene): EF633986.

16. **Nocardioides dubius** Yoon, Lee and Oh 2005d, 2211[VP]

du′bi.us. L. masc. adj. *dubius* doubtful of the taxonomic position.

Characteristics are as described for the genus and listed in Table 215, Table 216, and Table 217. Information presented below is based on the original description (Yoon et al., 2005d; Yoon et al., 2010), unless indicated.

Cells are irregular rods (0.8–1.0 × 1.5–2.5 µm) in the exponential phase of growth and show rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. Motile; a single flagellum was observed. Neither substrate nor aerial mycelia is formed. Colonies are irregular, raised with erose margins, yellowish-white in color and 2.0–3.0 mm in diameter after 3 d incubation on nutrient agar (NA; Difco) at 30°C. Grows at 10 and 37°C, but not at 4 or 38°C. Grows in up to 5% (w/v) NaCl, but better without addition of NaCl in trypticase soy broth (TSB; Difco). Optimal pH for growth is 7.0–8.0; grows at pH 6.0 and 10.5, but not at pH 5.5 (initial pH values; examined on NA as a basal medium after 10 d incubation at 30°C). Nutritionally non-exacting; grows on a mineral salts medium (ISP 9) with glucose and some other substrates (Table 215) as carbon-plus-energy source and an ammonium salt as sole

*Bacto Yeast Nitrogen Base medium without amino acids (Difco) supplemented with Casamino acids (10 mg per liter) and agar (15 g per liter), and neutralized by K_2HPO_4.

nitrogen source. Does not utilize D-cellobiose, D-fructose, sucrose, and D-xylose (Yoon et al., 2010); conflicting data were reported by Dastager et al. (2010) using the same basal medium (ISP 9). Utilizes glutamate and pyruvate as a sole carbon and energy sources in the same basal medium, but not benzoate, citrate, formate, and L-malate. Table 216 shows the carbon sources in the Biolog GP2 test system that are oxidized. Tweens 20, 40, and 60 are not hydrolyzed. The composition of the major polar lipids is unique: phosphatidylethanolamine, along with diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol [cells for analysis were grown in NB (Difco) at 30°C]. The major fatty acids (more than 3% of the total in at least one experiment) determined in cells harvested from NA after 6 and 7 d incubation at 30°C were $C_{16:0}$ iso (58.5 and 57.8%), $C_{17:0}$ 10-methyl (7.0 and 8.7%), $C_{16:0}$ 10-methyl (4.2 and 5.3%), $C_{18:0}$ iso (4.3 and 3.0%), $C_{16:1}$ iso (3.7 and 5.1%), $C_{17:0}$ iso (3.2 and 2.4%), and $C_{14:0}$ iso (2.5 and 3.0%). TBSA (2.7%) was detected only in the 6-d-old culture (among fatty acids exceeding 0.5%). The fatty acid profile of 7-d-old culture of *Nocardioides dubius* differed from those of *Nocardioides jensenii* and *Nocardioides daedukensis* (analyzed under the same experimental conditions) in the proportion of iso-branched acids, which was larger contributing nearly 75%, and in the proportions of some individual components (for details, see the descriptions of *Nocardioides jensenii* and *Nocardioides daedukensis* in this chapter and the paper of Yoon et al., 2010). The mean DNA–DNA relatedness of the type strain to the type strain of *Nocardioides daedukensis* was 19% (Yoon et al., 2010). The type strain (and the only strain described) was isolated by the standard dilution plating technique on a tenfold-diluted NA with the pH 10.0 adjusted using Na_2CO_3 (30°C).

Source (type strain): alkaline soil, Kwangchun, Korea.

DNA G+C content (mol%): 70.6 (HPLC).

Type strain: KSL-104, KCTC 9992, JCM 13008.

Sequence accession no. (16S rRNA gene): AY928902.

17. **Nocardioides exalbidus** Li, Xie and Yokota 2007a, 2449[VP] (Effective publication: Li, Xie and Yokota 2007b, 24.)

ex.al.bi′dus. L. masc. adj. *exalbidus* whitish, referring to the color of the colonies.

Characteristics are as described for the genus and listed in Table 215 and Table 220. Additional information presented below is based on the original description (Li et al., 2007b).

Cells are nonmotile, coccoid- to rod-shaped (~ 0.5 µm wide, up to 2.0 µm long), predominantly coccoid or very short rods (~0.6–0.8 µm in diameter) when grown 2 d on ISP 2 agar at 30°C, and show rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. Colony color is white, as observed on trypticase soy agar (TSA; BBL) and on IAM-A1 agar (that is a modified Detmer's medium; see IAM Catalog of Strains, 2004). Grows at 15–35°C, optimally at 30°C, and over a pH range of 6.0–9.0, with the optimal pH around 7.0. The organism grows in a mineral salts medium (IAM-A1 agar) with glucose as carbon-plus-energy source and nitrate as sole nitrogen source. The type strain utilizes amygdalin, 2-keto-gluconate, and 5-keto-gluconate as sole carbon and energy sources but not gluconate, gentiobiose, D-lyxose, sorbose, D-tagatose, D-turanose, adonitol, D- and L-arabitol, dulcitol, erythritol, sorbitol, xylitol, methyl β-D-xyloside, methyl α-D-mannoside, methyl α-D-glucoside, arbutin, starch, and glycogen.

Diphosphatidylglycerol and phosphatidylinositol were reported as major polar lipids; no phosphatidylcholine was detected. The main fatty acids determined in culture grown on TSA for 3 d at 27°C, included $C_{16:0}$ iso (28.0%), TBSA (18.2%), $C_{17:0}$ 10-methyl (7.7%), $C_{17:0}$ iso (9.1%), $C_{17:0}$ anteiso (6.9%), and $C_{18:0}$ (5.8%), and $C_{17:1}$ ω6*c* (4.7%). The DNA–DNA relatedness of the type strain of *Nocardioides exalbidus* to the type strains of phylogenetically neighboring species was 44% (*Nocardioides oleivorans*) and 39% (*Nocardioides ganghwensis*). Selected phenotypic characteristics useful in distinguishing *Nocardioides exalbidus* from the above and other phylogenetically closely related species are listed in Table 220. The type strain (the only strain characterized) was isolated from a lichen sample that was washed and crushed in sterilized water, followed by streaking the effluent on IAM-A1 agar medium, after incubation for 2 weeks and purification on TSA.

Source (type strain): lichen, Izu-Oshima Island, Japan.

DNA G+C content (mol%): 74 (HPLC).

Type strain: RC825, IAM 15416, JCM 23199, CCTCC AA206016.

Sequence accession no. (16S rRNA gene): AB273624.

18. **Nocardioides fonticola** Chou, Cho, Arun, Young and Chen 2008, 1866[VP]

fon.ti′co.la. L. masc. n. *fons*, *fontis* a spring, fountain; L. suff. *-cola* (from L. masc. or fem. n. *incola*) an inhabitant of a place; N.L. n. *fonticola* an inhabitant of a fountain or spring.

Characteristics are as described for the genus and listed in Table 215. Information presented below is based on the original species description (Chou et al., 2008).

Cells are nonmotile rods (~ 0.8 × 2.0–9.0 µm). Colonies on R2A (Difco) are pale yellowish, approximately 0.9–1.0 mm in diameter after 3 d incubation at 25°C, and reach a maximum of 2 mm after 5 d of incubation. Grows at 25–37°C, with optimum at 30°C. Grows at low salinity (0.5–1.0%, w/v, NaCl; optimum at 0.5%), but not in the absence of NaCl or at 2% (w/v) NaCl as assessed in nutrient broth prepared according to the Difco formula without NaCl. The pH range for growth is 5–9 (optimum pH 7–8), as examined in nutrient broth (Difco) with appropriate buffers; no growth is observed at pH 4.5 or 9.5 under the same experimental conditions. No acid is produced by oxidation of D-glucose, D-xylose, D-mannitol, maltose, D-lactose, sucrose, D-ribose, and glycogen (API Coryne test system). Negative for fermentation of glucose, and for assimilation of gluconate, malate, caprate, adipate, citrate, and phenylacetate (API 20NE). Positive for pyrazinamidase and pyrrolidonyl arylamidase. Tweens 20, 40, and 60 are hydrolyzed. Corn oil is not degraded. Sensitive to the following antibiotics (µg per disk): ampicillin (10), chloramphenicol (30), gentamicin (10), kanamycin (30), novobiocin (30), rifampin (5), penicillin G (10), streptomycin (10), and tetracycline (30). Resistant to nalidixic acid (30), ceftizoxime (30), or sulfamethoxazole (23.75) plus trimethoprim (1.25). Major fatty acids detected for cells harvested from

R2A after 3 d incubation at 25°C included $C_{16:0}$ iso (19.9%), $C_{17:0}$ (19.9%), $C_{17:1}$ ω8*c* (13.3%), $C_{18:1}$ ω9*c* (11.7%), $C_{18:0}$ (4.8%), $C_{18:0}$ iso (4.5%), as well as $C_{19:1}$ ω11*c* and/or $C_{19:1}$ ω9*c* (8.3%), 10-methyl-branched fatty acids [10-Me-$C_{17:0}$ (2.6%) and TBSA (1.7%)], and other acids [$C_{16:0}$, $C_{19:0}$, and $C_{17:0}$ iso (each 2.6–3.6%)]. The type strain (and the only strain described) was isolated by plating a water sample on R2A agar medium and incubation at 25°C for 3 d.

Source (type strain): freshwater of spring, Kaoshiung County, Taiwan.

DNA G+C content (mol%): 71.8 (HPLC).

Type strain: NAA-13, BCRC 16874, JCM 16703, LMG 24213.

Sequence accession no. (16S rRNA gene): EF626689.

19. **Nocardioides furvisabuli** Lee 2007b, 37[VP]

fur.vi.sa′bu.li. L. neut. adj. *furvum* black-colored; L. neut. n. *sabulum* gravel, sand; N.L. gen. n. *furvisabuli* of black-colored sand, the source of isolation of the type strain.

Characteristics are as described for the genus and listed in Table 215 and Table 220. Information presented below is based on the original publication (Lee, 2007b).

Cells are short motile rods (0.4–0.5 × 0.6–1.2 μm) after 3 d in culture at 30°C on YE/SW agar (ISP 2 medium prepared in 60%, v/v, natural sea water), and tend to adhere and form palisades (Figure 258). Colonies are yellow and 0.6–0.8 mm in diameter after 5 d incubation under the same conditions. The organism shows good growth on ISP 2 medium, marine agar (MA; Difco), and nutrient agar (Difco) with or without the addition of natural sea water. Prefers not to grow on standard trypticase soy agar (Difco). Grows at 4–37°C, with optimum at 30°C. The reported pH range for growth is pH 5.1–10.1 (initial pH of media), and the optimum is about 7.0. Grows in up to 6% (w/v) NaCl, as determined in ISP 2 as the basal medium. Nutritionally non-exacting; grows in a suitable mineral salts medium with glucose as carbon-plus-energy source and an ammonium salt as sole nitrogen source (e.g. ISP 9 medium). Citrate, formate, malate, succinate, tartrate, adonitol, D-dulcitol, and methyl α-D-mannoside but not benzoate, D-arabinose, L-sorbose, dextran, methyl α-D-glucoside, *meso*-erythritol, D-xylitol, and 2,3-butanediol are utilized as sole carbon and energy sources. Weakly positive for utilization of acetate, D-sorbitol, and 1,2-propanediol. Negative for acid production (API 20NE) from glucose. Elastin is degraded. The fatty acid profiles were reported for cells grown for 5 d at 30°C on YE/SW agar and MA agar. In the YE/SW culture, $C_{16:0}$ iso (34.1%), $C_{18:1}$ ω9*c* (27.2%), $C_{18:0}$ (7.9%), and $C_{16:0}$ (7.5%) were predominating; the straight-chain saturated acids comprised 17.1% of the total, and straight-chain unsaturated acids comprised almost 33%. Cells grown on MA agar had a significantly larger proportion (44%) of straight-chain saturated components, including $C_{18:0}$ (19.3%) and $C_{16:0}$ (14.6%) and a smaller proportion of straight-chain unsaturated acids (10.5%). The other major acids were $C_{16:0}$ iso (19.6%), $C_{18:1}$ ω9*c* (6.5%), $C_{16:1}$ iso (7.2%), and $C_{15:0}$ anteiso (7.5%). Notably, cells grown on MA agar had anteiso-branched acids ($C_{15:0}$ and $C_{17:0}$; 9.6% in sum), whereas cells grown on YE/SW had one 10-methyl-branched acid (10-Me-$C_{17:0}$; 1.7%). The polar lipid pattern (determined for cells harvested from YE/SW broth after 3 d incubation at 30°C) for *Nocardioides* is unique: phosphatidylcholine, phosphatidylglycerol, phosphatidylinositol, and an unidentified phospholipid. Selected phenotypic characteristics differentiating *Nocardioides furvisabuli* from the phylogenetically closely related species are listed in Table 220. The type strain (the only strain described) was isolated on ISP 4 medium prepared with 60% (v/v) natural sea water.

Source (type strain): black sand, Samyang Beach on Jeju Island, Korea.

DNA G+C content (mol%): 69.1 (HPLC).

Type strain: SBS-26, JCM 13813, NRRL B-24465.

Sequence accession no. (16S rRNA gene): DQ411542.

20. **Nocardioides ganghwensis** Yi and Chun 2004, 1298[VP]

gang.hwen′sis. N.L. masc. adj. *ganghwensis* of or belonging to Ganghwa island in Korea, the geographical origin of the type strain.

Characteristics are as described for the genus and listed in Table 215 and Table 220. Information presented below is based on the original species description (Yi and Chun, 2004a), unless indicated.

Cells are nonmotile irregular rods (~0.4–0.5 × 0.9–4.5 μm) in 3-d-old culture on marine agar (Difco). Colonies on marine agar (MA; Difco) are ivory, butyraceous, and approximately 1–2 mm in diameter after 3 d at 30°C and reach a maximum diameter of 3–4 mm after 5 d. Substrate or aerial mycelium is not observed. Grows at 10–40°C (with no growth at 5 and 50°C), at initial pH 6–10 (no growth at pH 5 and 11), and in the presence of NaCl up to 8% (w/v), as assayed on synthetic ZoBell medium (ZoBell, 1941).* The best growth is observed at 30°C, pH 7, and at a low NaCl concentration (1% or less). Nutritionally non-exacting; grows on a suitable mineral salts medium (e.g. ISP 9) with glucose as sole carbon-plus-energy source and an ammonium salt as sole nitrogen source (Lee, 2007b). The type strain utilizes acetate, citrate, succinate, L-asparagine, L-ornithine, and *N*-acetylglucosamine and other substrates (Table 215) as sole carbon and energy sources in mineral salts medium (Baumann et al., 1971) supplemented with 2% (v/v) Hutner's mineral base (Cohen-Bazire et al., 1957) and modified by reducing the concentration of sea salts to half-strength. Benzoate, tartrate, L-arginine, L-lysine, acetamide, and D-sorbitol are not used under the same test conditions. According to Lee (2007b), the organism can also utilize maltose, melibiose, and trehalose. L-Rhamnose is utilized as a carbon source for growth and energy (Schippers et al., 2005; Yi and Chun, 2004a); a conflicting result was reported by Lee (2007b) with ISP 9 as the basal medium. Crude oil is not degraded (Schippers et al., 2005). No acid production from glucose (API 20NE kit). Major fatty acids determined for cells grown at 30°C on MA for 3 d included $C_{16:0}$ iso (30.4%), $C_{17:1}$ ω8*c* (25.7%), $C_{18:1}$ ω9*c* (5.7%), $C_{16:1}$ iso H (4.4%), and $C_{17:0}$ 10-methyl (3.9%). Other fatty acids (various saturated, unsaturated, iso- and anteiso-branched and hydroxylated fatty acids) were present in smaller quantities.

*ZoBell medium: Bacto agar (Difco) 15 g; Bacto peptone (Difco), 5 g; yeast extract (Difco), 1 g; ferric citrate, 0.1 g; sea salts, 40 g; distilled water, 1 liter; sea salts were not added when the relation to NaCl was tested.

TBSA was not detected under the test conditions employed. The DNA–DNA similarity to the phylogenetically closest species, *Nocardioides oleivorans* and *Nocardioides exalbidus*, was respectively 32% (Schippers et al., 2005) and 39% (Li et al., 2007b). Selected phenotypic characteristics differentiating *Nocardioides ganghwensis* from these and other phylogenetically closely related species are listed in Table 220. The type strain (the only strain described) was isolated using R2A (Difco) supplemented with artificial sea salts (Sigma).

Source (type strain): sediment sample of getbol (tidal flat), Ganghwa Island, South Korea (37°35′31.9″N; 126°27′ 24.5″E).

DNA G+C content (mol%): 72 (HPLC).

Type strain: JC2055, IMSNU 14028, KCTC 9920, JCM 12124.

Sequence accession no. (16S rRNA gene): AY423718.

21. **Nocardioides ginsengisoli** Cui, Lee and Im 2009, 3048[VP]

gin.sen.gi.so′li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of soil of a ginseng field, the source of the organism.

Characteristics are as described for the genus and listed in Table 215, Table 218, Table 219, and Table 221. Information presented below is taken from the original species description (Cui et al., 2009).

Cells are nonmotile, slender, short rods (~ 0.2–0.4 × 0.8–1.2 μm) after culture on R2A agar (Difco) for 3 d at 30°C. Colonies developed under the same growth conditions are light yellow–white and convex. Grows at 15–37°C (optimum, 30°C), but not at 4 or 42°C after 5 d incubation. Growth occurs at pH 5.0–8.5, with optimum at pH 7.0, and in up to 5.0% (w/v) NaCl (assessed on R2A agar as basal medium after culture for 5 d). The organism grows on nutrient agar (Difco) and mineral salt medium* supplemented with glucose as a sole carbon source for growth-plus-energy, vitamins (Widdel and Bak, 1992), trace element solution SL-10 (Widdel et al., 1983), and selenite/tungstate solution (Tschech and Pfennig, 1984), but not on MacConkey agar. Utilizes n-nitrophenol (50 p.p.m.) and dibenzofuran (50–150 p.p.m.) as well as the following compounds as sole carbon and energy sources in the above basal medium: D-lyxose, pyruvic acid, acetate, propionate, 3-hydroxybutyrate, valerate, phenylacetate, benzoic acid, 3- and 4-hydroxybenzoate, malate, oxalate, gluconate, L-alanine, arginine, asparagine, aspartic acid, glutamic acid, glutamine, glycine, histidine, isoleucine, leucine, lysine, phenylalanine, L-proline, L-serine, threonine, tryptophan, tyrosine, and valine. The organism is unable to use the following substrates as sole carbon sources under the same test conditions: L-fucose, L-sorbose, citrate, formate, malonate, glutaric acid, tartaric acid, adipate, caprate, itaconate, maleinate, suberate, ethanol, methanol, dulcitol, D-sorbitol, xylitol, amygdalin, glycogen, dextran, cysteine, and methionine. Voges–Proskauer reaction is observable. Tests for degradation of chitin and xylan are negative. No acid or gas is produced from glucose. Nitrate is not used as a terminal electron acceptor in R2A broth supplemented with KNO_3 (10 mM) and thioglycolate with incubation under a nitrogen gas atmosphere. The fatty acid profiles determined for the type strain of this and closely related species are displayed in Table 219. Other selected phenotypic characteristics useful in preliminary discriminating *Nocardioides ginsengisoli* from the closely related species are listed in Table 218. DNA–DNA relatedness of the *Nocardioides ginsengisoli* type strain to the type strains of the phylogenetically closest species were 22–33% (Table 221). The type strain (the only strain described) was isolated from a soil sample suspended in 50 mM phosphate buffer (pH 7.0). After serial dilution with the same phosphate buffer, the suspension was spread on plates with one-fifth strength modified-R2A agar†, and the plates were incubated at 30°C for 1 month.

Source (type strain): soil of a ginseng field, Pocheon province, South Korea.

DNA G+C content (mol%): 70.2 (HPLC).

Type strain: Gsoil 1124, KCTC 19135, CCUG 52478, DSM 17921, JCM 16930.

Sequence accession no. (16S rRNA gene): AB245396.

22. **Nocardioides halotolerans** Dastager, Lee, Ju, Park and Kim 2009c, 1555[VP] (Effective publication: Dastager, Lee, Ju, Park and Kim 2008a, 26.)

ha.lo.to′le.rans. Gr. n. *hals halos* salt; L. part. adj. *tolerans* tolerating; N.L. part. adj. *halotolerans*, salt-tolerating, referring to the ability of the organism to tolerate high salt concentrations.

Characteristics are as described for the genus and listed in Table 215 and Table 216. Information presented below is taken from the original species description (Dastager et al., 2008a).

Cells are irregular rods (normally about 0.6 μm but may be 0.9 μm in diameter, up to 3.4 μm in length) on twofold diluted R2A agar plates at 28°C. A 7-d-old culture is mostly composed of coccoid cells and very short rods, up to 1 μm long. Data on motility are conflicting. Colonies are cream-white and 1–2 mm in diameter after 3 d under the same growth conditions. Nutritionally non-exacting; grows in a suitable mineral salts medium (e.g. ISP 9) with glucose as a sole carbon-plus-energy source and an ammonium salt as a sole nitrogen source. Also grows on twofold dilute R2A medium with up to 10% (w/v), optimally 3%, NaCl. Acid production from carbohydrates is rather uncommon or weak; no acid formed from any of the carbon sources tested. The major fatty acids determined for cells harvested from twofold-diluted R2A after incubation at 28°C for 7 d included $C_{16:0}$ iso (59.29%), $C_{17:0}$ anteiso (8.2%), $C_{18:1}$ ω9*c* (6.8%) and 10 methyl-$C_{16:0}$ (5.6%). The type strain (and the only strain described) was isolated by diluting plating method on tenfold-diluted R2A.

Source (type strain): farming soil, Bigeum Island, South Korea.

DNA G+C content (mol%): 69.7 (HPLC).

Type strain: MSL-23, KCTC 19274, DSM 19273.

Sequence accession no. (16S rRNA gene): EF466122.

*Mineral salt medium: 1.8 g of K_2HPO_4, 1.08 g of KH_2PO_4, 0.5 g of $NaNO_3$, 0.5 g of NH_4Cl, 0.1 g of KCl, 0.1 g of $MgSO_4$, and 0.05 g of $CaCl_2$ per 1 liter.

† One-fifth strength modified-R2A agar (per liter of distilled water): 0.25 g of tryptone, 0.25 g of peptone, 0.25 g of yeast extract, 0.125 g of malt extract, 0.125 g of beef extract, 0.25 g of Casamino acids, 0.25 g of Soytone, 0.5 g of glucose, 0.3 g of soluble starch, 0.2 g of xylan, 0.3 g of sodium pyruvate, 0.3 g of K_2HPO_4, 0.05 g of $MgSO_4$, 0.05 g of $CaCl_2$, and 15 g of agar.

23. **Nocardioides hankookensis** Yoon, Kang, Lee and Oh 2008, 437[VP]

han.ko.o.ken′sis. N.L. masc. adj. *hankookensis* of or belonging to Hankook, the Korean name of South Korea from where the type strain was isolated.

Characteristics are as described for the genus and listed in Table 215. Information presented below is based on the original species description (Yoon et al., 2008), unless indicated.

Cells are nonmotile irregular rods (0.4–0.8 µm in width, 1.5–10 µm in length). No coccoid cells are observable if grown on R2A (Difco) or trypticase soy agar (Difco) at 25°C. Neither substrate nor aerial mycelium is formed. Gram-stain-positive, but Gram-stain variable in old cultures. Colonies on R2A agar are white in color and 0.7–1.0 mm in diameter after 7 d incubation at 25°C. Grow at 10 and 34°C (optimum, 25°C), but not at 4 or 35°C, at pH 5.5–8.0, but not at pH 5.0 or 8.5 [in trypticase soy broth (Difco) with the pH adjusted by HC1 or Na_2CO_3], and in the presence of 0–2% (w/v) NaCl (optimum 0–0.5%), but not 3% NaCl (in a complex medium prepared according to the Difco trypticase soy broth formula, except that NaCl was omitted). Utilizes gentiobiose (weak), turanose, adipate, gluconate (weak), and malate as carbon sources, but not D-arabinose, D-lyxose, D- and L-fucose, sorbose, D-tagatose, L-xylose, adonitol, D-arabitol, dulcitol, erythritol, sorbitol, xylitol, caprate, citrate, 2- and 5-ketogluconate, phenylacetate, methyl β-D-xyloside, methyl α-D-mannoside, methyl α-D-glucoside, glycogen, and amygdalin (API 20NE and API 50 CH; AUX suspending medium). Tweens 20, 40, and 60 are decomposed. Tributylin is hydrolyzed (Song et al., 2011). Weak activity for cystine arylamidase, β-galactosidase, and trypsin, as well as tyrosine hydrolysis, but the test results vary between experiments or test methods (Song et al., 2011; Yoon et al., 2008). The type strain is susceptible to the following antibiotics (µg per disc, unless indicated otherwise): carbenicillin (100), chloramphenicol (100), gentamicin (30), kanamycin (30), lincomycin (15), neomycin (30), oleandomycin (15), polymyxin B (100 U), and streptomycin (50), but resistant to ampicillin (10), cephalothin (30), novobiocin (5), and penicillin G (20 U). The type strain is also sensitive to rifampin (30 µg) but reports on its tetracycline (30 µg) sensitivity conflict (Song et al., 2011). Major fatty acids (>5% of the total) of cells grown on R2A agar for 7 d at 25°C were $C_{16:0}$ iso (42.7%), $C_{17:1}$ ω8*c* (14.8%), $C_{18:1}$ ω9*c* (13.1%), $C_{17:0}$ 10-methyl (5.5%), and TBSA (2.3%). A different fatty acid profile was reported for cells grown on double-strength R2A agar plates for 3 d at 30°C (Song et al., 2011). The most pronounced differences were in a smaller proportion of $C_{16:0}$ iso (9.1%) and a larger proportion of total straight-chain saturated acids (26.3%) with $C_{14:0}$ predominating (10.2%). Song et al. (2011) reported the fatty acid profiles for the type strains of *Nocardioides hankookensis* and phylogenetically related species (*Nocardioides aquiterrae*, *Nocardioides pyridinolyticus*, and *Nocardioides caricicola*) obtained under the same experimental conditions.

The type strain exhibited DNA–DNA hybridization levels of 19 and 22% with the type strains of phylogenetically closest species, *Nocardioides aquiterrae* and *Nocardioides pyridinolyticus*, respectively. Phenotypic characteristics useful in distinguishing *Nocardioides hankookensis* from both above species include the cell appearance, size and non-motility, a lower growth temperature optimum and maximum, a lower DNA G+C content, the ability to produce esterase (C4), growth on L-arabinose and D-melibiose, sensitivity to rifampin (30 µg per disc), as well inability to reduce nitrate and produce α-glucosidase (Song et al., 2011; Yoon et al., 2004, 2008; Table 215). The type strain (and the only strain described) was isolated by the standard dilution plating technique at 25°C with tenfold-diluted nutrient agar (Difco).

Source (type strain): soil, Dokdo Island, Korea (37°14′12″N, 131°52′07″E).

DNA G+C content (mol%): 71.3 (HPLC).

Type strain: DS-30, JCM 15302, KCTC 19246, CCUG 54522.

Sequence accession no. (16S rRNA gene): EF555584.

24. **Nocardioides humi** Kim, Srinivasan, Park, Sathiyaraj, Kim and Yang 2009b, 2725[VP]

hu′mi. L. gen. n. *humi* of/from soil, pertaining to the source of isolation of the type strain.

Characteristics are as described for the genus and listed in Table 215. Information presented below is taken from the original species description (Kim et al., 2009b).

Cells incubated on Luria–Bertani (LB) agar at 30°C for 18 h are small rods (0.3–0.5 × 0.8–1.0 µm) and motile with peritrichous flagella (Figure 262). Colonies developed on R2A agar (Difco) after 3 d at 30°C are irregular, flat, and pale yellow in color. Grows at 25 and 42°C (the maximal temperature tested) optimally at 30–37°C, but not at 4°C. Optimal pH for growth is 6.5–7.5, the pH growth range is 5–11. L-Alanine, L-proline, L-serine, glycogen, 2-ketogluconate, 3-hydroxybutyrate, acetate, gluconate, itaconate, malate, propionate, and valerate (API 20NE, API 32GN), but not D-sorbitol, L-histidine, 3-hydroxybenzoate, 4-hydroxybenzoate, 5-ketogluconate, adipate, caprate, citrate, lactate, malonate, phenylacetate, and suberate are utilized as carbon sources. No acid produced from glucose (API 20NE). The major fatty acids (>5%) determined in cell mass harvested from TSA after 2 d incubation at 30°C included $C_{16:0}$ iso (23.1%), $C_{17:0}$ iso (16.2%), $C_{18:1}$ ω9*c* (11.8%), TBSA (9.7%), $C_{17:1}$ ω6*c* (7.7%), $C_{18:0}$ (6.0%), and $C_{16:0}$ (5.2%). The type strain (the only strain described) was isolated using the standard dilution-plating method on a tenfold-diluted R2A agar.

Source (type strain): surface soil of a ginseng field, South Korea.

DNA G+C content (mol%): 71.0 (HPLC).

Type strain: DCY24, JCM 14942, JCM 17026, KCTC 19265, LMG 24128

Sequence accession no. (16S rRNA gene): EF623863.

25. **Nocardioides hwasunensis** Lee, Lee and Kim 2008, 280[VP]

hwa.sun.en′sis. N.L. masc. adj. *hwasunensis* of or belonging to Hwasun, the place where the type strain was isolated.

Characteristics are as described for the genus and listed in Table 215 and Table 220. Information presented below is based on the original species description (Lee et al., 2008).

Nonmotile short rods (0.4–0.7 × 1.0–1.7 μm), occurring singly, in pairs, or in aggregates, are observed in young cultures grown in marine broth (MB; Difco) or in trypticase soy broth at 30°C. Shorter rods, and oval or coccoid cells are observed in older cultures. Colonies are yellowish cream in color on Marine agar (MA; Difco) and light yellow on ISP 2 agar or trypticase soy agar (TSA; Difco). Grows at 4–37°C (optimum, 30°C) but not at 42°C. Grows at pH 5.1 and 9.1, but not at pH 10.1 (on MA with pH adjusted using HC1 or NaOH) and in 4% (w/v) NaCl, but not in 5% (w/v) NaCl (on ISP 2 as the basal medium). Nutritionally non-exacting; grows on a suitable mineral salts medium with glucose as sole carbon-plus-energy source and an ammonium salt as sole nitrogen source (e.g. ISP 9 medium). Acid is produced from glucose by oxidation (API 20NE system), but glucose is not fermented. Acetate, citrate, formate (weak), malate, succinate, tartrate, D-sorbitol, and dextran are used as sole carbon and energy sources, but not D-arabinose, L-sorbose, adonitol, D-dulcitol, *meso*-erythritol, D-xylitol, 2,3-butanediol, 1,2-propanediol, benzoate, methyl-β-D-glucoside, methyl-β-D-mannoside. Utilization of L-arabinose is variable between strains, with the type strain showing positive reaction. The ability to hydrolyze gelatin varies among strains. The fatty acid profiles determined for cells grown on TSA at 30°C for 3 d were almost identical for two strains studied. The major fatty acids (>5%) for the type strains were as follows: $C_{16:0}$ iso (27.8%), $C_{16:0}$ (10.8%), $C_{18:0}$ (8.8%), $C_{18:1}$ ω9*c* (8.2%), $C_{15:0}$ iso (7.5%). 10-Methyl-branched acids were represented by TBSA (4.5%), 10-Me-$C_{17:0}$ (3.5%), and 10-Me-$C_{16:0}$ (2.9%). Selected characteristics differentiating *Nocardioides hwasunensis* from the phylogenetically closely related species are listed in Table 220. The two described strains (HFW-18 and HFW-21) were isolated from a water sample using ISP 2 medium prepared with 60% (v/v) natural sea water.

Source (type strain): water, the area, where running water from a valley merges into sea water on Hwasun beach, Jeju Island, Korea.

DNA G+C content (mol%): 71.1–72.2 (HPLC); 71.1 for the type strain.

Type strain: HFW-21, DSM 18584, JCM 15307, KCTC 19197.

Sequence accession no. (16S rRNA gene): AM295258.

26. **Nocardioides insulae** Yoon, Kang, Lee and Oh 2007b, 138[VP]

in.su′la.e. L. fem. gen. n. *insulae* of an island, referring to the source of isolation of the type strain.

Characteristics are as described for the genus and listed in Table 215. Information presented below is based on the original species description (Yoon et al., 2007b).

Cells are irregular rods (0.6–1.0 × 1.3–6.0 μm) or cocci in the exponential phase of growth and show rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. Neither substrate nor aerial mycelium is formed. Colonies are ivory in color and 1.0–1.5 mm in diameter after 7 d incubation on nutrient agar (NA; Difco) at 30°C.

Grows at 10 and 34°C (optimally at 30°C), but not at 4 or 35°C, and at low NaCl concentration [up to 3%, w/v, in trypticase soy broth (Difco formula without NaCl)]. Media without the addition of NaCl are preferable for growth. Growth is optimal at pH 8.0, observed at pH 6.5, but not observed at pH 6.0 [tested in Nutrient broth (Difco) adjusted to various pH values by the addition of HCl or Na_2CO_3]. In the API 20E test, acetate, L-malate, pyruvate, L-glutamate, and salicin (weakly), but not citrate, succinate, benzoate or formate are utilized as sole carbon and energy sources. Tweens 20, 40, and 60 are hydrolyzed. The type strain is susceptible to the following antibiotics (μg per disk, unless indicated): carbenicillin (100), cephalothin (30), chloramphenicol (100), gentamicin (30), kanamycin (30), lincomycin (15), neomycin (30), oleandomycin (15), polymyxin B (100 U), streptomycin (50), tetracycline (30), but not ampicillin (10), novobiocin (5), or penicillin G (20 U). The predominant fatty acid, as determined in cells harvested from NA plates after incubation at 30°C for 7 d, was $C_{16:0}$ iso (49.7%). The amounts of TBSA (8.3%), $C_{17:0}$ 10-methyl (2.9%), $C_{18:1}$ ω9*c* (7.4%), $C_{17:1}$ ω6*c* (5.4%), $C_{17:0}$ anteiso (4.9%), and other acids typical of the genus were smaller. The type strain (and the only strain described) was isolated on tenfold-diluted NA at 30°C using the standard dilution plating technique.

Source (type strain): soil, Dokdo Island, Korea.

DNA G+C content (mol%): 71.1 (HPLC).

Type strain: DS-51, JCM 15308, KCTC 19180, DSM 17944.

Sequence accession no. (16S rRNA gene): DQ786794.

27. **Nocardioides islandensis** Dastager, Lee, Ju, Park and Kim 2009d, 1555[VP] (Effective publication: Dastager, Lee, Ju, Park and Kim 2008e, 405.)

is.lan.den′sis. N.L. masc. adj. *islandensis* from or pertaining to Bigeum Island in Korea, from where the type strain was isolated.

Characteristics are as described for the genus and listed in Table 215. Information presented below is taken from the original species description (Dastager et al., 2008e).

Cells (cultured 10 d on R2A agar or twofold-diluted R2A at 28°C) are mostly slender irregular rods (ca. 0.5–0.6 μm in diameter, up to 3.7 μm in length) with nearly flat (just after division) and rounded ends. Short chains and branching forms may occur. Coccoid cells and larger spherical or club-shaped forms may be up to 1.6 μm in diameter. Nonmotile. Colonies are white to cream in color, moist and approximately 1–2 mm in diameter after 3 d incubation R2A agar at 28°C. Aerial mycelium is not formed. Nutritionally non-exacting; grows on ISP 9 with glucose as the carbon-plus-energy source and an ammonium salt as the sole nitrogen source. Acid production from carbohydrates is rather uncommon or weak; no acid formed from any of the carbon sources examined (the test method, not reported). Acetoin not produced. The major fatty acids (cells from R2A agar plates after incubation for 10 d at 28°C) included (% of the total): $C_{18:1}$ ω7*c* (50.3), $C_{16:0}$ (11.5), $C_{14:0}$ (7.5), $C_{16:0}$ iso (4.2), and $C_{15:0}$ anteiso (4.2); other acids ($C_{15:0}$ iso, $C_{17:1}$ ω8*c*, $C_{18:0}$, $C_{18:1}$ ω5*c*, $C_{17:0}$ iso, $C_{17:0}$ anteiso, and $C_{17:0}$) each contributed 1–1.9%. No TBSA was detected (limit, 1%).

The type strain (and the only strain described) was isolated by the standard dilution plating on tenfold-diluted R2A agar at 28°C.

Source (type strain): farming soil, Bigeum Island, Korea.

DNA G+C content (mol%): 71.4 (HPLC).

Type strain: MSL-26, KCTC 19275, DSM 19321.
Sequence accession no. (16S rRNA gene): EF466123.

28. **Nocardioides jensenii** (Suzuki and Komagata 1983b) Collins, Dorsch and Stackebrandt 1989, 3[VP] (*Pimelobacter jensenii* Suzuki and Komagata 1983b, 673[VP]; effective publication: Suzuki and Komagata 1983c, 69.)

jen.se′ni.i. N.L. gen. masc. n. *jensenii* of Jensen; named after H.L. Jensen, the Danish bacteriologist who contributed to the taxonomy of coryneform bacteria.

Characteristics are as described for the genus and listed in Table 215, Table 216, and Table 217. Information presented below based on the descriptions of Suzuki and Komagata (1983b), Collins et al. (1989), Yi and Chun (2004a, 2004b), and Yoon et al. (2010) unless otherwise indicated.

Cells are nonmotile irregular rods [mostly 0.6–0.8 × 2.0–4.0 μm or longer, up to 7.0 μm, after culture 1 d on YM agar (0.5% Bacto-peptone, 0.3% yeast extract, 0.3% malt extract, 1% glucose, and 2% agar)] can undergo a distinct rod–coccus morphogenetic cycle. Branching cells and V-forms occasionally occur, but neither substrate nor aerial mycelium is formed. Week-old cultures on YM agar are mostly coccoid cells and very short rods (0.6–1.0 × 0.8–1.0 μm) arranged singly, in pairs, short chains, or small clusters. Colonies are white, yellowish white, and may be light yellowish gray in older cultures on some media. A yellowish soluble pigment may be occasionally produced in older cultures, e.g. on Chapek's agar with glucose instead of sucrose. Grows at 18 and 37°C, but not at 42°C; in 5% (w/v) NaCl, but not in 10% NaCl. The ability to grow in 7% (w/v) NaCl was reported (Nesterenko et al., 1985b). Nutritionally non-exacting; grows in a suitable mineral salts medium with glucose as sole carbon-plus-energy source and an ammonium salt or nitrogen as sole nitrogen source. The type strain of *Nocardioides jensenii* can degrade dinitro-*o*-cresol herbicides (Gundersen and Jensen, 1956). Assimilates acetate, but shows no alkaline reaction with citrate and succinate (in tests described by Yamada and Komagata, 1972). The type strain utilizes acetate, pyruvate, L-asparagine, L-lysine (weak), but not succinate, acetamide, L-arginine, L-ornithine, and D-sorbitol as sole carbon and energy sources for growth (Yi and Chun, 2004a). Uses azelate, suberate, thymine, and uracil, but not tetradecane as sole carbon and energy sources (Collins et al., 1994). Some test results displayed in Table 215, including citrate and benzoate utilization, may vary among experiments or test methods (Dastager et al., 2010; Yi and Chun, 2004a; Yoon et al., 2010). No acid produced during glucose oxidation in the API 20NE test (Yi and Chun, 2004a) or in conventional tests in peptone-based media. The test results for oxidation of carbon substrates (Tóth et al., 2008) obtained with the Biolog GP2 system are shown in Table 217.

The cell-wall peptidoglycan contains LL-A_2pm, glycine, alanine, and glutamic acid. The peptidoglycan type is A3γ (A41.1; http://www.peptidoglycan-types.info), as reported by Schleifer and Kandler (1972) for the type strain *Nocardioides jensenii* (*Arthrobacter simplex* NCIB 9770). Conflicting data on the composition of peptidoglycan (with three-glycine interpeptide bridge) was reported by Collins et al. (1989). Re-examination of the data for the type strain of *Nocardioides jensenii* (L. Evtushenko and L. Dorofeeva, unpublished) showed the molar ratio of alanine, glutamate, LL-A_2pm, and glycine to be 2.1:1.0:1.0:1.2, which is similar to the peptidoglycan composition reported by Schleifer and Kandler (1972). The sugars detectable in the cell wall include galactose, glucose, and rhamnose, along with *N*-acetylglucosamine and glycerol (Takeuchi and Yokota, 1989; Tul'skaya, 2009) and minor amounts of mannose (Tul'skaya, 2009). The cell wall contains teichoic acid of unidentified structure, which involves glycerol, galactose, *N*-acetylglycosamine, and pyruvate as components, along with phosphate (Takeuchi and Yokota, 1989; Tul'skaya, 2009). The polyamine pattern of the type strain grown in rich (R) medium (Yamada and Komagata, 1972) includes cadaverine as the predominant component (54%), followed by putrescine (22%), spermidine (12%), spermine (9%), and 1,3-diaminopropane (2.5%) (Busse and Schumann, 1999). The major isoprenoid quinone is MK-8(H_4), with isoprenyl units saturated at sites II and III.

Fatty acid composition depends on the culture conditions and analytical procedures (Miller et al., 1991; Schumann et al., 1997; Suzuki and Komagata, 1983a, 1983c; Yoon et al., 2010; Yoon et al., 1997b). The fatty acids [for cells harvested from nutrient agar (NA, Difco) after 4 and 7 d cultivation at 30°C] included $C_{16:0}$ iso (45.5 and 33.4%), $C_{16:1}$ iso (14.0 and 10.9%), $C_{17:1}$ (8.7 and 10.1%), $C_{18:1}$ (3.2 and 4.6%), $C_{15:0}$ iso (3.7 and 4.0%), $C_{17:0}$ iso (1.7 and 2.1%), $C_{18:0}$ iso (2.7 and 1.2%), $C_{18:0}$ (2.0 and 2.9%), $C_{17:0}$ 10-methyl (5.4 and 5.5%), $C_{16:0}$ 10-methyl (2.5 and 6.4%), TBSA (2.4 and 9.5%), and other fatty acids characteristic of the genus, each contributing 0.3–1.4% (Yoon et al., 2007b; Yoon et al., 2010). The major fatty acids (for cells grown in TSB medium for 24–48 h at 28°C) included $C_{16:0}$ iso (28.6%), $C_{15:0}$ iso (16.7%), $C_{18:1}$ (10.3%), $C_{17:0}$ iso (9.6%) and $C_{17:1}$ (6.5%), with TBSA constituting 2.4% (Schumann et al., 1997). A larger proportion of TBSA (19.1%), along with similar amounts of $C_{17:0}$ 10-methyl (5.3%), $C_{16:0}$ 10-methyl (3.6), and $C_{16:0}$ iso (34%), was reported by Miller et al. (1991). In some experiments, 2-hydroxy fatty acids may be detected (O'Donnell et al., 1982; Suzuki and Komagata, 1983c; Suzuki and Komagata, 1983a). Diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol and supposedly hydroxy-phosphatidylglycerol were the principal polar lipids (Collins et al., 1989). Susceptible to some actinophages (Collins et al., 1989) that multiply in mycelium-forming *Nocardioides* strains (Prauser, 1976; Prauser, 1984a; Prauser, 1989). The mean DNA–DNA relatedness was 16% to the type strains of *Nocardioides albus* and *Nocardioides simplex*, 13% to the type strain of *Terrabacter tumescens* (membrane filter method with tritium-labeled DNA; Suzuki and Komagata, 1983c), and 10% to *Nocardioides daedukensis* (Yoon et al., 2010; procedure of Ezaki et al., 1989). The type strain (the only strain described) was isolated as a herbicide-decomposing bacterium (Jensen and Gundersen, 1956).

Source (type strain): soil.

DNA G+C content (mol%): 68.8 (T_m).

Type strain: ATCC 49810, CCUG 37988, CIP 102404, CNF 091, DSM 20641, IAM 12581, IFO (now NBRC) 14755, KCTC 9134, NBRC 14755, JCM 1364, LMG 16325, NCIB (now NCIMB) 9770, VKM Ac-1878.

Sequence accession no. (16S rRNA gene): AF005006, X53214.

Additional remarks: the type strain of this species was originally identified as a strain of *Arthrobacter simplex* (Jensen and Gundersen, 1956). Suzuki and Komagata (1983c) proposed to reclassify it as *Pimelobacter jensenii.* Collins et al. (1989) transferred this species to *Nocardioides* as *Nocardioides jensenii* (see *Further descriptive information* for more details).

29. **Nocardioides kongjuensis** Yoon, Lee, Jung, Kim, Kim and Oh 2006b, 1786[VP]

kong.ju.en′sis. N.L. masc. adj. *kongjuensis* of or belonging to Kongju, Korea, pertaining to the geographical origin of the type strain.

Characteristics are as described for the genus and listed in Table 215, Table 218, Table 219, and Table 221. Information presented below is from Yoon et al. (2009, 2006b), unless indicated.

Cells are irregular rods (0.4–0.7 × 0.8–3.0 µm) in the exponential phase of growth and exhibit rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. Neither substrate nor aerial mycelium is formed. Colonies are yellowish white in color, reaching 3.0–5.0 mm diameter after 3 d incubation on nutrient agar (NA; Difco) at 30°C. Grows at 10 and 40°C, but not at 4 or 41°C, at pH 5.5, but not at pH 5.0 [optimum, 7.0–8.0; nutrient broth (NB; Difco) with the pH adjusted with HCl or Na_2CO_3 prior to sterilization], and in up to 5% (w/v) NaCl, with optimal growth in the absence of NaCl (trypticase soy broth prepared according to the Difco formula without NaCl).

Nutritionally non-exacting; grows on a suitable mineral salts medium (e.g. ISP 9 medium) with glucose as sole carbon-plus-energy source and an ammonium salt as sole nitrogen source. The organism is capable of degrading *N*-hexanoyl-L-homoserine lactone and using this compound as a sole source of carbon and energy for growth. L-Arabinose, D-mannose (weak), malate, succinate, and pyruvate are utilized as carbon sources, but not D-fructose, acetate, benzoate, citrate, and formate (basal medium ISP 9). In the API 20NE or API 50 CH (AUX as suspending medium) test, D-fructose, adipate, citrate (weak), gluconate, and malate were used, but not D- and L-arabinose, D- and L-fucose, gentiobiose, D-lyxose, D-mannose, D-melibiose, L-rhamnose, L-sorbose, D-tagatose, D-turanose, L-xylose, D-adonitol, D-and L-arabitol, dulcitol, erythritol, D-sorbitol, xylitol, methyl α-D-mannoside, methyl α-D-glucoside, methyl β-D-xyloside, *N*-acetylglucosamine, amygdalin, arbutin, esculin, starch, glycogen, 2- and 5-ketogluconate, caprate, and phenylacetate. In conventional tests with mineral salts medium supplemented with vitamins and element solution, this organism used L-alanine, L-histidine, L-proline, L-serine, acetate, 3- and 4-hydroxybenzoic acids, 3-hydroxybutyrate, malic acid, propionic acid, suberic acid, and valeric acid as sole carbon sources for growth, but not lactate, itaconate, and malonate (Cui et al., 2009). Tweens 20, 40, and 60 are hydrolyzed. Acetoin is produced (Cui et al., 2009). For cells harvested from NB agar after incubation at 30°C for 6 d, the fatty acids (5% or more of the total) included $C_{16:0}$ iso (27.1%), TBSA (14.4%), $C_{17:0}$ 10-methyl (6.0%), $C_{17:1}$ ω6*c* (11.2%), $C_{18:1}$ ω9*c* (5.0%), and $C_{17:0}$ iso (6.3%). A different fatty acid profile was reported for cells grown on trypticase soy agar (Difco) at 30°C for 2 d (Table 219). The fatty acids composition of the type strain of *Nocardioides kongjuensis* and type strains of related species are compared in Table 219. A 21–46% DNA–DNA similarity was found between the type strain of *Nocardioides kongjuensis* and the type strains of phylogenetically closest species (Table 221). Selected phenotypic characteristics differentiating *Nocardioides ginsengisoli*, *Nocardioides caeni*, and other phylogenetically related species are listed in Table 218. The type strain (the only strain described) was isolated using minimal medium (Leadbetter and Greenberg, 2000) supplemented with *N*-hexanoyl-L-homoserine lactone as the carbon source and NH_4Cl as the nitrogen source; pH 6.5 (for further details on the isolation procedure see Yoon et al., 2006b).

Source (type strain): soil, Kongju, South Korea.

DNA G+C content (mol%): 72.1 (HPLC).

Type strain: A2-4, KCTC 19054, JCM 12609.

Sequence accession no. (16S rRNA gene): DQ218275.

30. **Nocardioides koreensis** Dastager, Lee, Ju, Park and Kim 2008f, 2294[VP]

ko.re.en′sis. N.L. masc. adj. *koreensis* of or pertaining to Korea, the geographical origin of the type strain.

Characteristics are as described for the genus and listed in Table 215. Information presented below is based on the original species description (Dastager et al., 2008f).

Cells are typically irregular rods (mostly 0.4–0.7 µm wide, up to 3.2 µm long). The irregular rods do not exceed 2 µm in length and coccoid cells occasionally occur after 7 d of incubation in R2A medium (Difco) at 28°C (Figure 255). Branching cells may be observed. Motility is reported. Colonies are cream to whitish in color, flat, and 0.9–1.4 mm in diameter after 4–5 d incubation in R2A medium at 30°C. No aerial or substrate mycelium is formed. Optimum growth is at pH 7.0–8.0 and 30°C. Grows at 27–37°C, but not at 25°C or above 37°C, and in up to 5% (w/v) NaCl (in twofold-diluted R2A medium). The carbon sources for growth tested according to Kämpfer (1991) by using mineral salts medium supplemented with yeast extract, Oxoid (0.02 g/l), bio-Lactysat, bioMérieux (0.02 g/l), a vitamin solution, and trace element solution (Kämpfer et al., 1990) are listed in Table 215. The major fatty acids reported for cells harvested from twofold-diluted R2A broth (pH 7.5) after incubation for 10 d at 28°C included (% of the total): $C_{16:0}$ iso (62.9%), $C_{18:1}$ ω9*c* (5.9%), $C_{14:0}$ iso (4.0%), $C_{17:0}$ 10-methyl (3.4%), $C_{16:0}$ (3.3%), $C_{16:1}$ iso (3.1%). Neither TBSA nor hydroxylated fatty acids were reported among components equal or exceeding 1% of the total fatty acids. The type strain (and the only strain described) was isolated using a tenfold-diluted R2A.

Source (type strain): soil, Bigeum Island, South Korea.

DNA G+C content (mol%): 69.9 (HPLC).

Type strain: MSL-09, DSM 19266, JCM 16022, KCTC 19272.

Sequence accession no. (16S rRNA gene): EF466115.

31. **Nocardioides kribbensis** Yoon, Kim, Lee and Oh 2005b, 1614[VP]

krib.ben′sis. N.L. masc. adj. *kribbensis* pertaining to KRIBB, arbitrary adjective formed from the acronym of the Korea Research Institute of Bioscience and Biotechnology, KRIBB, where taxonomic studies on this species were performed.

Characteristics are as described for the genus and listed in Table 215. Information presented below from the original publication (Yoon et al., 2005b).

Cells are irregular rods (0.8–1.0 × 1.5–2.0 µm) in the exponential phase of growth and can undergo a rod-to-coccus morphogenetic cycle from the early exponential phase to the stationary phase. Neither substrate nor aerial mycelium is formed. Gram-stain-positive; Gram-staining is variable in old cultures. Colonies are cream in color and 1.0–1.5 mm in diameter after 6 d incubation on twofold diluted NA (pH 9.0). Grows at 4 and 35°C but not at 36°C, and in up to 3% (w/v) NaCl. Growth occurs at pH 6.0 and 11.0, with optimum growth at pH 9, but not at pH 5.5 or pH 12 [in twofold diluted NA adjusted to alkaline pH with Na_2CO_3 (below pH 10.5) or KOH (above pH 10.5)]. Nutritionally non-exacting; grows on a suitable mineral salts medium (e.g. on ISP 9) with glucose as sole carbon-plus-energy source and an ammonium salt as sole nitrogen source. D-Sorbitol but not adonitol is used as a carbon source. Tweens 20, 40, and 60 are hydrolyzed. The predominant fatty acids of three strains of this species [harvested from twofold-diluted NA (pH 9.0) after incubation for 5 d at 30°C] were almost identical and that of the type strain (% of the total) were: $C_{16:0}$ iso (42.5), $C_{15:0}$ iso (9.7), $C_{18:1}$ ω9*c* (7.2), $C_{17:0}$ iso (5.7), $C_{14:0}$ iso (5.4), $C_{17:0}$ anteiso (4.2), $C_{16:0}$ (3.6), and TBSA (1.2%). DNA–DNA relatedness between the three strains of this species were 88–93%. Mean DNA–DNA hybridization values of 28.7% and 18% were reported between the type strain of *Nocardioides kribbensis* and type strains of *Nocardioides basaltis* and *Nocardioides salarius*, respectively (Kim et al., 2008a; Kim et al., 2009a). DNA–DNA relatedness of strains of *Nocardioides kribbensis* to the type strain of *Nocardioides aquiterrae* was 8–15% (Yoon et al., 2005b). The three described strains of this species were isolated on tenfold-diluted NA with pH adjusted to 10.0 using Na_2CO_3.

Source (type strain): alkaline soil, Korea.

DNA G+C content (mol%): 73–74 (HPLC); 74 for type strain.

Type strain: KSL-2, DSM 16314, JCM 13594, KCTC 19038.

Sequence accession no. (16S rRNA gene): AY835924.

32. **Nocardioides lentus** Yoon, Lee and Oh 2006a, 274[VP]

len′tus. L. masc. adj. *lentus* slow, delayed, referring to slow growth.

Characteristics are as described for the genus and listed in Table 215. Characteristics presented below taken from the original description (Yoon et al., 2006a).

Cells are irregular rods (0.4–0.7 × 1.0–4.5 µm) in the exponential phase of growth and can undergo rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. Neither substrate nor aerial mycelium is formed. Gram-stain-positive; staining is variable in old cultures. Colonies are yellow in color and 0.5–1.0 mm in diameter after 10 d incubation on twofold diluted nutrient agar (NA; Difco) at 28°C. Grows at 4 and 34°C, but not at 35°C, at pH 6.5 and 9.5, but not at pH 6.0 or 10.0 [initial pH of the test medium, twofold diluted nutrient broth (Difco) adjusted prior to sterilization with HCl or Na_2CO_3], and optimally at pH 8.0. Growth occurs in up to 5% (w/v) NaCl, and is optimal in 0.5% [w/v; as assessed using trypticase soy broth (Difco)]. Nutritionally non-exacting; grows on a suitable mineral salts medium (e.g. ISP 9 medium) with glucose as sole carbon-plus-energy source and an ammonium salt as sole nitrogen source. Lactose and D-xylose are also used as carbon sources by some strains, including the type strain. Utilizes D-sorbitol but not adonitol as a carbon source. Positive for hydrolysis of Tweens 20, 40, and 60; hydrolysis of tyrosine is variable among strains and positive for the type strain. The fatty acids of the type strain (cells harvested from twofold diluted NA [pH 8.0] after incubation for 10 d at 28°C) included $C_{16:0}$ iso (60.9%), $C_{17:1}$ ω8*c* (6.6%), and $C_{17:0}$ 10-methyl (5.8%) as well as TBSA (1.6%), a hydroxylated fatty acid ($C_{17:0}$ iso 3-OH; 2.7%) and minor amounts of other fatty acids characteristic of *Nocardioides*. One strain of this species, KSL-18, was found to contain $C_{16:0}$ iso in the highest proportion (81.9%) reported for the genus *Nocardioides* so far. Strains KSL-17, KSL-18, and KSL-19 are identical in their 16S rRNA gene sequences and exhibit 85–90% DNA–DNA hybridization to each other. The type strain and both reference strains described were isolated by the standard dilution plating technique on tenfold-diluted NA with the pH adjusted to 9.0 using Na_2CO_3 at 30°C.

Source (type strain): alkaline soil, Kwangchun, Korea.

DNA G+C content (mol%): 74.6–74.8 (HPLC).

Type strain: KSL-17, DSM 16315, JCM 14046, KCTC 19039.

Sequence accession no. (16S rRNA gene): DQ121389 for the type strain and DQ121390 and DQ121391 for the reference strains KSL-18 and KSL-19, respectively.

33. **Nocardioides luteus** Prauser 1985, 223[VP] (Effective publication: Prauser 1984b, 647.) ("*Nocardioides flavus*" Ruan and Zhang 1979, 347; "*Nocardioides fulvus*" Ruan and Zhang 1979, 350.)

lu′te.us. L. masc. adj. *luteus* yellow, referring to the yellow primary mycelium of the type strain.

Characteristics are as described for the genus and listed in Table 215. Information presented below is based on the author's description (Prauser, 1984b, 1989) and recent observations, unless indicated.

The branching hyphae of the primary mycelium are usually yellow on most ISP media to orange-yellow (oatmeal agar, glycerol-nitrate agar) or cream to faintly yellowish-brown on some peptone-containing media, particularly in aged cultures. The aerial mycelium is white or cream-colored if well developed. No pronounced soluble pigments are usually produced, but a light reddish-brown or light yellowish-brown pigment may be observable in older cultures on some media. Colonies lacking aerial mycelium are usually pasty on most media, with smooth to wrinkled and dull to bright surfaces. Growth is optimum at about 28°C, observable at 10°C and 42°C, and may occur at 45°C but not at 50°C. The organism grows well in up to 8% (w/v) NaCl (weak growth at 9%) and at initial pH values of 5–9, but not at pH 10, as assessed using a complex medium, PYGP (peptone, 0.5%; yeast extract, 0.3%; glucose, 0.5%; K_2HPO_4, 0.02%). Nutritionally non-exacting; grows aerobically on a suitable mineral salts medium (e.g. ISP 9) with glucose or sucrose as carbon-plus-energy source and an ammonium salt or nitrate as sole nitrogen source. Growth

and biomass production is enhanced in the presence of vitamins (Lawson et al., 2000a) and traces of yeast extract or peptone. Acids are produced from D-glucose, L-arabinose, D-xylose, D-mannitol, and D-fructose under aerobic conditions in conventional tests; some strains may produce acids from L-rhamnose and sucrose. However, no acid production from glucose was observed with the API 20NE system (Yi and Chun, 2004a). Citrate, succinate, and benzoate but not tartrate are used as carbon sources. The type strain also utilizes acetate but not acetamide, L-arginine, L-asparagine, L-lysine, L-ornithine, and D-sorbitol as a sole carbon sources (Yi and Chun, 2004a), uses azelate, malonate, suberate, L-proline, tetradecane, and phenol as sole carbon and energy sources (Collins et al., 1994). Uses D-fructose, L-rhamnose and sucrose as carbon sources, and can hydrolyze xanthine, but the test results may vary between experiments or test conditions (Prauser, 1984b; Yi and Chun, 2004a). Relatively weak but distinct oxidase activity is observable (assessed with tetramethyl-*p*-phenylenediamine in young culture). Production of α-mannosidase was reported (Yi and Chun, 2004a).

Galactose is the only cell-wall monosugar which is clearly detectable in routine chemotaxonomic studies; traces of glucose and/or rhamnose may also be found (Shashkov et al., 2000b; Tul'skaya, 2009). The cell wall contains a 1,5-poly(ribitol phosphate) teichoic acid (Shashkov et al., 2000b), which is the most essential chemotaxonomic marker differentiating *Nocardioides luteus* from *Nocardioides albus* that possesses a poly (galactosylglycerol phosphate) polymer (see Further descriptive information for details). The major isoprenoid quinone is MK-8(H_4); minor amounts of MK-8(H_2) and MK-8 may be detected (O'Donnell et al., 1982). The type strain of *Nocardioides luteus* harvested from rich (R) medium (Yamada and Komagata, 1972) had nearly 6 μmol/g (dry wt) of polyamines, with the predominant compounds cadaverine (53.7%) and putrescine (28.2%), and lesser amounts of spermidine (11.3%), 1,3-diaminopropane (2.6%), spermine (2.4%), and tyramine (1.7%) (Busse and Schumann, 1999). The cellular fatty acid profile of the type strain of *Nocardioides luteus* is generally similar to that obtained for *Nocardioides albus* under the same experimental conditions (Miller et al., 1991; O'Donnell et al., 1982; Yoon et al., 1997b). In some experiments, a small quantity of a 3-hydroxy fatty acid may additionally occur (Yoon et al., 1997b) and a significantly larger proportion of TBSA may be detected (Miller et al., 1991). The qualitative polar lipid composition of the type strain of *Nocardioides luteus* is also generally reminiscent of that detected in *Nocardioides albus* (Figure 263). Susceptible to taxon-specific *Nocardioides* actinophages. The DNA–DNA hybridization levels between the type strains of *Nocardioides luteus* and *Nocardioides albus* were 49% and 38% in different experiments (Prauser. 1984a, 1989). The DNA–DNA relatedness of *Nocardioides albus* type strain to "*Nocardioides flavus*" 71-N54 (= DSM 46114) and "*Nocardioides fulvus*" 71-N86 (= DSM 46115) was 33% and 41%, respectively (Prauser, 1989).

Source (type strain): soli.

DNA G+C content (mol%): 67.5 (T_m).

Type strain: KCTC 9575, ATCC 43052, CCUG 37986, CIP 103450, DSM 43366, IMET 7830, JCM 3358, LMG 16209, IFO (now NBRC) 14491, VKM Ac-1246.

Sequence accession no. (16S rRNA gene): AF005007, X53212.

Additional remarks: some strains without distinct yellow pigmentation cited in the literature under the species name *Nocardioides albus* might also belong to *Nocardioides luteus* (see the section *Further descriptive information* for more details).

34. **Nocardioides marinisabuli** Lee, Hyun and Lee 2007, 2961[VP]

ma.ri.ni.sa'bu.li. L. adj. *marinus -a -um* of the sea, marine; L. neut. n. *sabulum* gravel, sand; N.L. gen. n. *marinisabuli* of sea sand, referring to the sand sample from which the type strain was isolated.

Characteristics are as described for the genus and listed in Table 215. Data presented below based on information published by Lee et al. (2007), unless indicated.

Cells are irregular rods (0.6–0.8 × 1.4–2.1 μm). Colonies are pale yellow in color approximately 1.0–1.5 mm in diameter after growth on trypticase soy agar (TSA; Difco) for 7 d.

Grows at pH 5.1–12.1, in up to 8% NaCl, as determined in the basal medium ISP 2, at 4–40°C but not at 42°C. Nutritionally non-exacting; grows on a suitable mineral salts medium with glucose as the carbon-plus-energy source and an ammonium salt as the sole nitrogen source (e.g. ISP 9 medium). Citrate and gluconate are assimilated, while D-arabinose, D-sorbitol, acetate, adipate, caproate, citrate, malate, and phenylacetate are not sole carbon and energy sources. Glucose is not fermented (API 20NE). The major fatty acids (in cells harvested from TSA and MA after 3 d incubation at 30°C) were mainly the same components but had slightly different proportions (% of the total): $C_{16:0}$ iso (48.7 and 35.9), $C_{17:0}$ iso (10.8 and 12.3), $C_{18:1}$ ω9*c* (5.6 and 15.4), $C_{17:1}$ ω8*c* (2.8 and 5.6), $C_{17:0}$ anteiso (4.3 and 4.1). Less than 1% TBSA was found in both experiments; the other 10-methyl-branched acid were $C_{17:0}$ 10-methyl (1.7%) and $C_{16:0}$ 10-methyl (<1%) for the MA culture and $C_{17:0}$ 10-methyl (3.2%) for the TSA culture. The fatty acid profile of the type strain of a phylogenetically close species, *Nocardioides basaltis* (grown on MA at 30°C for 3 d and analyzed using the same procedure) differed from that of *Nocardioides marinisabuli* mainly by having a larger proportion of $C_{16:0}$ iso (70%), smaller proportions of $C_{18:1}$ ω9*c* (2.8%), and traces of $C_{17:0}$ iso and $C_{17:0}$ anteiso (<1%). A larger proportion of $C_{16:0}$ iso (65.3%) was also detected in a younger culture of *Nocardioides salarius* grown on MA at 30°C (Kim et al., 2008a). The type strain of *Nocardioides marinisabuli* had DNA–DNA hybridization values of 33±9% and 15.8±1.5%, respectively, with type strains of the most closely related species (99.2% 16S rRNA gene sequence similarity) *Nocardioides salarius* and *Nocardioides basaltis* (Kim et al., 2008a, 2009a) and 23.1±5.6% (Park et al., 2008) and 18 ± 6% (Lee et al., 2007) with type strains of more distant species, *Nocardioides dokdonensis* and *Nocardioides kribbensis* (<97.7% sequence similarity). The type strain (the only strain described) was isolated using ISP 4 medium (Shirling and Gottlieb, 1966) prepared with 60% (v/v) natural sea water.

Source (type strain): sand, Samyang Beach, Jeju Island, Korea.

DNA G+C content (mol%): 73.1 (HPLC).

Type strain: SBS-12, DSM 18965, JBRI 2003, KCCM 42681

Sequence accession no. (16S rRNA gene): AM422448.

35. **Nocardioides marinus** Choi, Kim, Noh and Cho 2007, 778[VP]

ma.ri′nus. L. masc. adj. *marinus* of or belonging to the sea, from where the type strain was isolated.

Characteristics are as described for the genus and listed in Table 215. The data presented below are from Choi et al. (2007), unless indicated.

Cells are nonmotile small rods (0.4–0.6 × 1.0–1.8 µm) in the exponential phase and coccoid forms in the stationary phase. Colonies on marine agar (MA; Difco) are creamy white.

Grows at 10–40°C (optimum, 25–30°C) but not at 5 or 45°C, and in 0.5–8% (w/v) NaCl (optimum, 1–3%), but not 0% NaCl (test medium, ZoBell broth*; ZoBell, 1941). Utilizes L-asparagine, but not benzoate, citrate, succinate, tartrate, acetamide, L-arginine, L-lysine, and L-ornithine as a sole or principal carbon source for growth and energy. Glucose is not fermented (API 20NE). The major fatty acids in cells grown on MA agar plates at 30°C for 1 d included $C_{16:0}$ iso (71.5%), $C_{17:0}$ 10-methyl (5.1%), $C_{18:1}$ ω9*c* (4.4%), and $C_{17:1}$ ω8*c* (3.8%). Other components of the fatty acid profile were various saturated, monounsaturated, iso-, anteiso- and 10-methyl-branched fatty acids (0.3–2.1%), including TBSA (1.7%) and $C_{15:0}$ iso 2-OH and/or $C_{16:1}$ ω7*c* (1.3%). Level of DNA–DNA similarity (thermal denaturation and renaturation method) between the type strain of this species and the type strain of *Nocardioides terrae* was 16% (Zhang et al., 2009a). The type strain (the only strain described) was isolated using a selective S medium† (Fialho et al., 1999).

Source (type strain): sea water around Dokdo Island, the East Sea, Korea.

DNA G+C content (mol%): 72.9 (HPLC).

Type strain: CL-DD14, JCM 15615, KCCM 42321, DSM 18248.

Sequence accession no. (16S rRNA gene): DQ401093.

36. **Nocardioides mesophilus** Dastager, Lee, Pandey and Kim 2010, 2291[VP]

me.so.phi′lus. Gr. adj. *mesos* middle; Gr. adj. *philos* loving; N.L. masc. adj. *mesophilus* middle (temperature)-loving, i.e. mesophilic.

Characteristics are as described for the genus and listed in Table 215 and Table 216. Information presented below is taken from the original species description (Dastager et al., 2010).

Cells are slender short rods, 0.3–0.8 × 0.9–1.4 µm on R2A agar. Motility but no flagella were reported. Colonies are translucent, cream-whitish, and slightly raised after 2 d incubation at 28°C on twofold-diluted R2A agar. Optimum growth temperature and pH are 28°C and 7.0–7.5, respectively. Grows at 20–37°C. Acid is not produced from any of the carbon sources tested. Nutritionally non-exacting; grows on a mineral salts medium (ISP 9) with glucose as the carbon-plus-energy source and an ammonium salt as the sole nitrogen source. The major cellular fatty acids in cells harvested from R2A plates after incubation at 28°C for 7 d included $C_{16:0}$ iso (44.6%), $C_{16:1}$ (12.1%), $C_{14:0}$ iso (11.0%), $C_{16:0}$ (6.5%), $C_{18:1}$ ω9*c* (3.1%), $C_{16:0}$ 10-methyl (2.8%), $C_{15:0}$ iso (2.3%), and $C_{15:0}$ (2.2%). No TBSA was reported. DNA–DNA relatedness between the type strains of *Nocardioides mesophilus* and *Nocardioides jensenii* was 34±2.0% (Dastager et al., 2010). The type strain (and the only strain described) was isolated by serial dilution plating on tenfold-diluted R2A agar after 7 d incubation at 28°C.

Source (type strain): soil, Bigeum Island, Jeollanam-do Province, Korea.

DNA G+C content (mol%): 68.7 (HPLC).

Type strain: MSL-22, DSM 19432, KCTC 19310.

Sequence accession no. (16S rRNA gene): EF466117.

37. **Nocardioides nitrophenolicus** Yoon, Cho, Lee, Suzuki, Nakase and Park 1999, 679[VP]

ni.tro.phe.no′li.cus. N.L. n. *nitrophenol* nitrophenol; L. masc. suff. *-icus* suffix used with the sense of pertaining to; N.L. masc. adj. *nitrophenolicus* relating to nitrophenols.

Characteristics are as described for the genus and listed in Table 215, Table 218, Table 219, and Table 221. Information presented below is from Yoon et al. (1999, 2009, 2006b), unless indicated.

Cells are irregular rods (0.5–0.8 × 1.0–3.0 µm) in 2 d culture on nutrient agar and can undergo rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. Motile, a single flagellum was observed (Figure 261). Neither substrate nor aerial mycelium is produced. Gram-stain-positive but the Gram staining test result is variable in old cultures. Colonies are yellowish white on nutrient agar (NA; Difco). Grows at 15 and 40°C (optimum, 30°C) but not at 45 or 10°C, as assessed after one-month incubation on nutrient agar (NA, Difco), and at initial pH 6 and 10 (optimum, pH 8; tested on NA).

Nutritionally non-exacting; grows on a suitable mineral salts medium (e.g. ISP 9) with glucose and an ammonium salt as sole carbon and nitrogen sources. The organism is capable of utilizing phenol, *p*-nitrophenol, and dibenzofuran (at suitable concentrations in the test medium) as sole carbon sources for growth (Cui et al., 2009; Kubota et al., 2005a; Yoon et al., 1999; Table 218). D-Mannose (weak), acetate, fumarate, succinate are used as sole carbon and energy sources for growth with ISP9 as the basal medium, but not L-arabinose, lactose, maltose, D-melibiose, adonitol, D-mannitol, D-sorbitol, citrate, and benzoate. The organism can also grow on a mineral salts medium with L-arginine, but not with tartrate, L-asparagine, L-lysine, L-ornithine, acetamide, D-salicin, and *N*-acetylglucosamine as sole carbon sources (Yi and Chun, 2004a). In API 20NE or API 50 CH tests with AUX as suspending medium, adipate, gluconate, and malate were used as sole carbon sources but not D- and L-arabinose, D- and L-fucose, gentiobiose, D-lactose, D-melibiose, L-xylose, D-sorbose, D-tagatose, adonitol, D- and L-arabitol, dulcitol, erythritol, sorbitol, xylitol, methyl α-D-mannoside, methyl

*Zobell Broth: 5 g of Bacto peptone, 1 g of yeast extract, 0.1 g of ferric citrate, and 1 liter of distilled water.

†S medium: 10 g of Na_2HPO_4, 3 g of KH_2PO_4, 1 g of K_2SO_4, 30 g of NaCl, 0.2 g of $MgSO_4{\cdot}7H_2O$, 0.01 g of $CaCl_2$, 0.001 g of $FeSO_4{\cdot}7H_2O$, 1 g of Casamino acids, 1 g of yeast extract, 20 g of glucose, 20 g of Bacto agar, and 1 liter of distilled water.

α-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, esculin, starch, glycogen, citrate, 2-and 5-ketogluconate, caprate, and phenylacetate. According to Cui et al. (2009), the type strain grows with L-alanine, L-histidine, L-proline, L-serine, lactate, caprate, 3- and 4-hydroxybenzoic acids, 3-hydroxybutyrate, malic acid, propionate, suberate, valerate, as well as with maltose, D-mannose, D-mannitol, melibiose, and salicin as carbon and energy sources but not with adipate, itaconate, and malonate (tested on mineral salts medium supplemented with vitamins and an element solution). Acetoin is produced (Cui et al., 2009). According to Yi and Chun (2004a), the type strain cannot produce acid from glucose (API 20NE kit). Arbutin is weakly hydrolyzed. Elastin is not degraded.

Major fatty acids in cells harvested from NA after 4 d incubation at 30°C were $C_{16:0}$ iso (28.1%), TBSA (13.9%), $C_{17:1}$ ω6*c* (10.8%), $C_{17:0}$ iso (12.3%), $C_{17:0}$ anteiso (5.8%), $C_{17:0}$ 10-methyl (5.1%), $C_{16:0}$ 10-methyl (3.6%), $C_{18:1}$ ω9*c* (4.5%), and $C_{15:0}$ iso (3.1%). The major fatty acids for cells grown on trypticase soy agar (Difco) at 30°C for 2 d (Table 219) differed in having larger proportions of saturated iso-branched acids (61.7% in total, with $C_{16:0}$ iso contributing 39.8%) and saturated straight-chain acids (14.4%), smaller proportions of total 10-methyl-branched acids (5.7%) and the absence of 2-hydroxylated acids. *Nocardioides nitrophenolicus* is substantially distinguished from *Nocardioides simplex* and other species of this genus by the length of the 16S–23S ITS region (328 bp, the shortest among the analyzed strains) and the nucleotide sequences (Yoon et al., 1998a). Distinct differences from other species, including *Nocardioides simplex*, was also revealed in the RNase P RNA gene sequences (Yoon and Park, 2000). The DNA–DNA similarity values (Table 221) between the type strain of *Nocardioides nitrophenolicus* and the type strains of the closest species ranged from 22 to 49% (Cui et al., 2009; Kubota et al., 2005a; Yoon et al., 1999; Yoon et al., 2009; Yoon et al., 2006b). Selected phenotypic characteristics useful in distinguishing *Nocardioides nitrophenolicus* from phylogenetically close species are listed in Table 218. The type strain (the only strain described) was isolated using minimal salts medium supplemented with a trace element solution and *p*-nitrophenol for enrichment and subsequent isolation (for further details on the isolation procedure see Yoon et al., 1999).

Source (type strain): industrial wastewater, Cheong-ju, South Korea.

DNA G+C content (mol%): 71.4 (HPLC).

Type strain: NSP41, CIP 107017, DSM 15529, KCTC 0457BP, JCM 10703.

Sequence accession no. (16S rRNA gene): AF005024.

38. **Nocardioides oleivorans** Schippers, Schumann and Spröer 2005, 1502[VP]

o.le.i.vo′rans. L. n. *oleum* oil; L. v. *vorare* to devour; N.L. part. adj. *oleivorans* capable of utilizing oil (hydrocarbons).

Characteristics are as described for the genus and listed in Table 215 and Table 220. Information presented below is from the original description (Schippers et al., 2005), unless indicated.

Nonmotile, irregular rods (about 0.3 × 1.1 μm). Colonies (maximum diameter after 2 weeks, 2 mm) are translucent and orange-pigmented. Grows at 30°C and in 2% NaCl. According to the original species description, *N*-acetyl-D-glucosamine, acetate, propionate, fumarate, DL-3-hydroxybutyrate, DL-lactate, L-malate, pyruvate, L-aspartate, L-histidine, L-proline, putrescine, phenylacetate, L-ornithine, and other substrates but not aconitate, adipate, citrate, α-D-galacturonate, 3-hydroxybenzoate, 4-hydroxybenzoate, suberate, adonitol, sorbitol, L-alanine, L-hydroxyproline, L-serine, glycogen, and *N*-acetyl-D-galactosamine are utilized as sole carbon and energy sources (tested using a basal medium containing vitamins and trace elements (Kämpfer et al., 1991). Crude oil is also used as a growth substrate. Acid is not produced from D-glucose, rhamnose, sucrose, adonitol, inositol, xylose, or sorbitol under aerobic conditions in conventional tests (Kämpfer et al., 1991). Glucose is not fermented (API 20NE; Lee, 2007b). The following substrates are hydrolyzed: *p*-nitrophenyl (pNP) *N*-acetyl-β-D-glucosaminide, pNP β-D-galactopyranoside, pNP α-D-glucopyranoside, pNP β-D-glucopyranoside, pNP α-D-maltoside, bis-pNP phosphate, benzolphosphonacid pNP-ester, pNP phosphocholine, 2-deoxythymidine 5′-pNP phosphate, L-alanine *p*-nitroanilide (pNA), L-glutamate pNA, L-glutamate-γ-3-carboxy pNA, L-leucine pNA, and L-lysine pNA, whereas pNP *N*-acetyl-β-D-galactosaminide, pNP α-L-arabinopyranoside, pNP β-D-cellobioside, pNP β-D-glucuronide, pNP β-D-lactoside, pNP α-D-mannoside, pNP β-D-xyloside, glycine pNA, L-proline pNA, and L-valine pNA are not hydrolyzed. Some additional characteristics of this organism were reported by Lee (2007b). The cell-wall peptidoglycan is of A3γ-type (LL-A_2pm-glycine). MK-8(H_4) is the predominant menaquinone and MK-8(H_2) is a minor menaquinone component. The major fatty acids determined for cells grown in basal medium* included $C_{18:1}$ ω9*c* (27.5%), $C_{16:0}$ iso (18.6%), TBSA (9.0%), $C_{18:0}$ (7.5%), $C_{17:0}$ iso (6.6%), and $C_{17:1}$ ω6*c* (5.7%).

The DNA–DNA relatedness (using the spectrophotometric method) of the type strain of *Nocardioides oleivorans* to the type strain of the phylogenetically closest species, *Nocardioides ganghwensis* (99% 16S rRNA gene sequence similarity) was 32% whereas its relatedness to *Nocardioides exalbidus* (using the method of Ezaki et al., 1989) was 44% (Li et al., 2007b). Selected phenotypic characteristics useful in distinguishing *Nocardioides oleivorans* from phylogenetically closely related species are listed in Table 220. The type strain (the only strain described) was isolated by enrichment in mineral salts medium (Fedorak and Westlake, 1981) supplemented with crude oil (30°C; several weeks) and subsequent isolation on the complex oil-free medium (Bosecker et al., 1991; Schippers et al., 2005).

Source (type strain): crude oil sample, the oilfield Oerrel of the Gifhorn Trough, Germany.

DNA G+C content (mol%): not determined.

Type strain: BAS3, DSM 16090, JCM 14342, NCIMB 14004.

Sequence accession no. (16S rRNA gene): AJ698724.

*Basal medium: 23.4 g of NaCl, 0.75 g of KCl, 7.0 g of $MgSO_4 \cdot 7H_2O$, 0.5 g of peptone from meat, 0.5 g of peptone from casein, 1.0 g of yeast extract, and 18 g of agar per 1 liter of water; pH 7.3.

39. **Nocardioides panacihumi** An, Im, Lee and Yoon 2007, 2145[VP]

pa.na.ci.hu′mi. N.L. n. *Panax* scientific name of ginseng; N.L. gen. n. *panacis* of ginseng; L. n. *humus* soil; N.L. gen. n. *panacihumi* of soil of a ginseng field.

Characteristics are as described for the genus and listed in Table 215. Other characteristics presented below are from the original publication (An et al., 2007), unless indicated.

Cells are nonmotile, small irregular rods (0.3–0.5 × 0.7–1.2 μm), forming white colonies, after 3 d incubation on R2A agar at 30°C. Undergo rod-to-coccus morphogenesis from the early exponential phase to the stationary phase. No growth occurs on MacConkey agar.

Grows well at 30°C and at pH 7.0; growth occurs at 15 and 30°C and at pH 5.0–8.0, but not at 4 and 37°C and at pH 8.5. Prefers low salinity, growing on R2A agar in 1% (w/v) NaCl, but not in 2%. Acetate, gluconate, glycogen, 3-hydroxybenzoate, 4-hydroxybenzoate, 3-hydroxybutyrate, propionate, valerate, phenylacetate, L-alanine, and L-proline but not L-fucose, D-sorbitol, adipate, caprate, citrate, itaconate, 2- and 5-ketogluconate, L-lactate, malate, malonate, suberate, L-histidine and L-serine are utilized as sole carbon sources. Acids are produced from D-glucose, D-fructose, D-lyxose, D-raffinose, L-rhamnose, sucrose, D-turanose, and *N*-acetylglucosamine (API 50 CH), but not from D- and L-fucose, gentiobiose, D-lactose, D-lyxose, D-mannose, melezitose, melibiose, L-sorbose, D-tagatose, L-xylose, adonitol, arabitol, dulcitol, erythritol, glycerol, inositol, D-mannitol, D-sorbitol, xylitol, gluconate, 2- or 5-ketogluconate, starch, glycogen, arbutin, inulin, salicin, methyl α-glucopyranoside, methyl α-D-mannoside, or methyl β-D-xyloside. In API 50 CH tests, acids are also not produced from cellobiose, D-galactose, maltose, D-ribose, and trehalose (characteristics that differentiate this species from the phylogenetically close species *Nocardioides terrae*; Zhang et al., 2009a). Glucose is not fermented (API 20NE). Nitrate reduction is weak under aerobic conditions. Catalase-positive (Cho et al., 2010), oxidase negative (Zhang et al., 2009a). Xylan and chitin are not degraded. The major fatty acids of cells harvested from R2A agar after incubation for 6 d at 30°C were $C_{16:0}$ iso (45.5%), $C_{17:1}$ ω6*c* (7.5%), $C_{16:0}$ (6.4%), and $C_{17:0}$ (5.9%); the minor fatty acids were TBSA and its homologs, as well as $C_{15:0}$ iso 3-OH. The DNA–DNA relatedness (thermal denaturation and renaturation method) of the type strains of *Nocardioides panacihumi* and *Nocardioides terrae* was 21% (Zhang et al., 2009a). To isolate the type strain (the only strain described), the sample was suspended in 50 mM phosphate buffer (pH 7.0) and seeded on one-fifth-strength R2A agar plates after serial dilution in the same buffer.

Source (type strain): soil of a ginseng field, Pocheon Province, South Korea.

DNA G+C content (mol%): 73 (HPLC).

Type strain: Gsoil 616, DSM 18660, JCM 15309, KCTC 19187.

Sequence accession no. (16S rRNA gene): AB271053.

40. **Nocardioides panacisoli** Cho, Lee, An, Whon and Kim 2010, 390[VP]

pa.na.ci.so′li. N.L. n. *Panax -acis* scientific name of ginseng; L. n. *solum* soil; N.L. gen. n *panacisoli* of soil of a ginseng field, the source of isolation of the organism.

Characteristics are as described for the genus and listed in Table 215. Information presented below is taken from the original species description (Cho et al., 2010).

Cells are slender short rods (0.2–0.4 × 0.8–1.2 μm) after 3 d in culture on R2A agar (Difco) at 30°C, forming light yellowish and convex colonies. Will grow within the temperature range of 10–42°C but not at 4 or 45°C, with the best growth at 18–37°C. Grows at pH 5.5–8.5 (on R2A agar prepared with suitable buffers). Grows on R2A agar with 2.0% (w/v) but not 3.0% NaCl. Grows in mineral salts medium (1.8 g of K_2HPO_4, 1.08 g of KH_2PO_4, 0.5 g of $NaNO_3$, 0.5 g of NH_4Cl, 0.1 g of KCl, 0.1 g of $MgSO_4$, and 0.05 g of $CaCl_2$ per 1 liter), supplemented with glucose, vitamins (Widdel and Bak, 1992), trace element solution SL-10 (Widdel et al., 1983), and selenite/tungstate solution (Tschech and Pfennig, 1984). Acetate, adipate, citrate, 3-hydroxybutyrate, gluconate, L-malate, L-proline, propionate, and valerate are also used as a sole carbon source for growth-plus-energy as tested on the above basal medium, but not the following compounds: L-alanine, caprate, L-fucose, glycogen, L-histidine, 3-hydroxybenzoic acid, itaconate, 5-ketogluconate, L-lactic acid, malonate, phenylacetate, L-serine, D-sorbitol, and suberate. The organism produces H_2S from sodium thiosulfate. Xylan or chitin is not degraded. Neither acid nor gas is produced from glucose (API 20E). Xylan or chitin is not degraded. Major fatty acids (>5% of the total) determined in cell mass scraped from trypticase soy agar Difco) after incubation at 30°C for 2 d included $C_{16:0}$ iso (28.0%), $C_{18:1}$ ω9*c* (10.7%), $C_{17:1}$ ω8*c* (9.0%), $C_{17:1}$ ω6*c* (5.8%), TBSA (6.7%), and $C_{16:0}$ (6.1%). The type strain (and the only strain described) was isolated according to the procedure and medium described by Cui et al. (2007b) for isolation of *Nocardioides ginsengisoli*; the plates were incubated at 30°C for 1 month under aerobic conditions.

Source (type strain): soil of a ginseng field in Pocheon Province, South Korea (37°58′N; 127°15′E).

DNA G+C content (mol%): 73.0 (HPLC).

Type strain: Gsoil 346, JCM 16953, KCTC 19470, DSM 21348.

Sequence accession no. (16S rRNA gene): FJ666101.

41. **Nocardioides plantarum** Collins, Cockcroft and Wallbanks 1994, 525[VP]

plan.ta′rum. N.L. gen. pl. n. *plantarum* of plants.

Characteristics are as described for the genus and listed in Table 215. Data presented below based on information published by Collins et al. (1994), unless indicated.

Cells are irregular rods (mean 0.4–0.7 × 0.8–2.4 μm or longer) in young culture and may produce V-forms. In older cultures, coccoid cells usually predominate. Nonmotile. Colonies are typically non-pigmented, but may be light brownish-gray in older cultures on some media. Growth occurs at 5 and 30°C, but not at 37°C (see Table 215) or in the presence of 5% NaCl. The organism grows well on nutrient agar (Difco) (Yi and Chun (2004a) and some other organic media based on yeast extract and peptone. Growth occurs with glucose and other sources (including fumarate, propionate, succinate, and isobutyrate) as sole or principal carbon sources on the basal mineral salts medium containing (per liter) mineral base E (Owens and Keddie, 1969), 0.2 g of Bacto Yeast Extract (Difco), 12 g of agar, 2 μg of

vitamin B_{12}, 10 mg of sodium glutamate, and 10 mg of methionine (Collins et al., 1994). Some strains utilize L-proline and tetradecane. Histidine, histamine, malonate, phenol, azelate, suberate, crotonate, pentoate, thymine, and uracil are not utilized. Tween 40 and Tween 60 are hydrolyzed. Hippurate is not decomposed. According to Lawson et al. (2000a), thiamine is requited as the only growth factor in a glucose-mineral salts medium (Grainger, 1963). However, the type strain can also grow with glucose or other substrates as sole carbon sources in minimal media without thiamine (Yi and Chun, 2004a), for instance on mineral salts medium (Baumann et al., 1971) supplemented with 2% (v/v) Hutner's mineral base (Cohen-Bazire et al., 1957) and modified by reducing the concentration of sea salts to half-strength. On the above basal medium, according to Yi and Chun (2004a), the type strain is able to grow with acetate, citrate, L-arginine, and L-ornithine as sole carbon sources, but not with benzoate, tartrate, D-sorbitol, L- and D-asparagine, L-lysine, and acetamide. No acid production from glucose (API 20NE kit) (Yi and Chun (2004a). The main component of the quinone system is MK-8(H_4); a minor amount of MK-7(H_4) is detectable. Neither cell-wall neutral monosugars nor cell-wall teichoic acids were revealed (Tul'skaya, 2009).

Polyamine pattern of the type strain grown in rich (R) medium (Yamada and Komagata, 1972) included cadaverine (33.9%) and spermine (42.4%) as the predominant components, with minor amounts of tyramine (11.9%), 1,3-diaminopropane (6.8%), and spermidine (5.1%) (Busse and Schumann, 1999). The major fatty acids reported for cells harvested after 1-d incubation on marine agar (Difco) at 30°C included $C_{16:0}$ (10.5%), TBSA (8.4%), $C_{18:0}$ (6.8%), $C_{16:0}$ iso (6.2%), $C_{17:0}$ 10-methyl (6.0%), $C_{10:0}$ (5.7%), and $C_{18:1}$ ω9*c* (5.0%) (Yi and Chun, 2004a). The main cellular fatty acids determined for the type strain grown in TSB medium at 28°C for 24–48 h included $C_{16:0}$ iso (26.0%), $C_{17:0}$ anteiso (16.8%), $C_{18:1}$ (15.7%), $C_{17:0}$ (6.1%), and $C_{17:0}$ iso (5.4%) (Schumann et al., 1997). The two strains described (Grainger J70 and Grainger J6) were isolated from herbage as reported by Grainger (1963).

Source (type strain): herbage.

DNA G+C content (mol%): 69 (T_m).

Type strain: Grainger J70, ATCC 51889, CIP 104157, DSM 11054, JCM 9626, LMG 16210, NCIMB 12834, VKM Ac-1998.

Sequence accession no. (16S rRNA gene): AF005008, X69973.

42. **Nocardioides pyridinolyticus** Yoon, Rhee, Lee, Park and Lee 1997b, 935[VP]

py.ri.di.no.ly'ti.cus. N.L. n. *pyridinum* pyridine; N.L. masc. adj. *lyticus* (from Gr. masc. adj. *lutikos*) able to loosen, able to dissolve; N.L. masc. adj. *pyridinolyticus* pyridine-dissolving.

Characteristics are as described for the genus and listed in Table 215. Data presented below based on information published by Yoon et al. (2008, 2004, 1997b), unless indicated.

Cells are small rods (0.5–0.6 × 1.2–1.6 μm) in young culture on minimal salts medium supplemented with 0.05% (w/v) yeast extract. Show rod-to-coccus morphogenesis from the early exponential phase to the stationary phase (Figure 259). Gram-stain-positive, but Gram straining is indistinct in old cultures. Motile, a single flagellum was observed (Figure 260). Neither substrate nor aerial mycelium is produced. Colonies are cream colored on nutrient agar (NA; Difco) and are approximately 1.0–1.5 mm in diameter after 5 d at 35°C. The organism grows well on minimal salts media supplemented with additional growth factors, yeast extract and tryptone, at pH 5 and 9 (optimum, pH 8) and at 20 and 40°C (optimum, 35°C). Utilizes pyridine and phenol as carbon and energy sources for growth, and also acetate, adipate, L-arabitol, turanose and other carbon sources (Table 215) as tested on basal Stevenson's medium* (Stevenson, 1967). The following substrates are not utilized on the same basal medium: D- and L-fucose, gentiobiose, D-lyxose, D-tagatose, sorbose, stachyose, adonitol, dulcitol, erythritol, D-sorbitol, xylitol, caprate, 2-ketogluconate, 5-ketogluconate, malate, phenylacetate, methyl α-D-glucoside, methyl α-D-mannoside, methyl β-D-xyloside, amygdalin, glycogen, esculin, and arbutin. According to Yi and Chun (2004b, 2004a), L-asparagine and succinate, but not benzoate, tartrate, L-arginine, L-lysine, L-ornithine, and acetamide are utilized as carbon and energy sources. Tributylin is hydrolyzed (Song et al., 2011). Data on utilization of D-galactose, lactose, D-mannose and D-mannitol as sole sources of carbon and energy vary between experiments or the test methods (Yi and Chun, 2004a, 2004b; Yoon et al. 1997b, 2004, 2008). Similarly, hydrolysis of tyrosine and production of cysteine arylamidase vary between experiments or test methods (Song et al., 2011; Yoon et al., 2008). Acid production from glucose is not observable with the API 20NE test system (Yi and Chun, 2004a, 2004b). Sensitive to tetracycline (30 μg) and shows resistance to ampicillin (10 μg), chloramphenicol (100 μg), streptomycin (50 μg), and rifampin (30 μg), as assessed using filter-paper discs (Song et al., 2011). The predominant menaquinone is MK-8(H_4); minor or trace amounts of MK-7(H_4) and MK-8(H_2) may occur. The major cellular fatty acids determined for cells harvested after 4 d incubation on nutrient agar (NA; Difco) at 30°C included $C_{16:0}$ iso (47.3%), $C_{17:0}$ anteiso (14.2%), $C_{15:0}$ iso (5.1%), $C_{17:0}$ 10-methyl (5.5%), $C_{16:0}$ 10-methyl (5.0%), TBSA (3.4%), and $C_{16:1}$ iso H (4.2%). A different fatty acid profile was recently reported for cells grown on 1/2-strength R2A agar (1/2-R2A) for 3 d at 30°C (Song et al., 2011). The most remarkable differences were in $C_{14:0}$ iso 3-OH (8.8%), $C_{18:1}$ ω5*c* (8.8%) and minor amounts of cyclic fatty acids, which were not mentioned among fatty acids exceeding 0.5% in cells grown on NA (Yoon et al. 1997a, 2004), as well as a smaller proportion of $C_{16:0}$ iso (22%). The fatty acid profiles of *Nocardioides pyridinolyticus* and phylogenetically close species (*Nocardioides aquiterrae*, *Nocardioides hankookensis*, and *Nocardioides caricicola*) grown on 1/S-R2A agar are compared by Song et al. (2011). The DNA–DNA relatedness of the type strains of *Nocardioides pyridinolyticus* to it closest phylogenetic relative, *Nocardioides aquaterrae* (99.2% 16S rRNA gene sequence similarity) were

*Stevenson's Medium: Bacto yeast nitrogen base medium without amino acids (Difco) supplemented with Casamino acids (10 mg per liter) and agar (15 g per

found to be 28.7 and 32.5% in reciprocal experiments using the procedure of Ezaki et al. (1989). Mean similarity to *Nocardioides hankookensis* using the same method was 22%. A higher DNA–DNA relatedness (53.5±5.5%) determined by the same method was reported for the pair *Nocardioides pyridinolyticus*–*Nocardioides caricicola* (Song et al., 2011). The characteristics useful in distinguishing *Nocardioides pyridinolyticus* from the phylogenetically closest species, *Nocardioides aquiterrae* and *Nocardioides hankookensis*, include the growth temperature range (higher optimal temperature for growth), cell motility, negative reaction in the test for cytochrome oxidase activity, the ability to grow with inositol, D-melezitose and D-ribose as sole carbon sources, and resistance to chloramphenicol (100 µg per disc), streptomycin (50 µg per disc), and probably the ability to utilize pyridine. The type strain (and the only strain taxonomically characterized) was isolated as described by Lee et al. (1991).

Source (type strain): oxic zone of an oil shale column.

DNA G+C content (mol%): 72.5 (HPLC).

Type strain: OS4, CIP 106800, DSM 15530, KCTC 0074BP, JCM 10369.

Sequence accession no. (16S rRNA gene): U61298.

43. **Nocardioides salarius** Kim, Choi, Hwang and Cho 2008a, 2062[VP]

sa.la′ri.us. L. masc. adj. *salarius* of salt, referring to the salt resistance of this micro-organism.

Characteristics are as described for the genus and listed in Table 215. Additional data presented below are based on information published by Kim et al. (2008a).

Cells are nonmotile rods (0.3–0.6 × 0.6–1.6 µm), forming creamy white colonies on marine agar (MA; Difco) MA at 30°C. Grows at 10–35°C, optimally at 25–30°C; no growth occurs at pH 5 or at temperatures 5 or 40°C. Salt-requiring; grows at NaCl concentrations of 1–10% (w/v), with optimum growth at 3% NaCl, as tested in ZoBell broth (ZoBell, 1941), containing 5 g of Bacto peptone, 1 g of yeast extract, 0.1 g of ferric citrate, and 1 liter of distilled water; no growth is observable at 0.5% (v/w) or without NaCl in the same test medium. Growth occurs in marine broth at initial pH values of 6 and 10 (the highest value examined); the optimum pH for growth is 6–7. A number of carbon sources (Table 215), as well as L-arginine and L-ornithine enhance growth in a basal mineral salts medium* supplemented with 0.05 g of yeast extract. Citrate, succinate, L-asparagine, and L-lysine are not used as sole or principal carbon sources. Glucose is not fermented (API 20NE). The predominant fatty acid detected in cells harvested from MA after 1 d incubation at 30°C was $C_{16:0}$ iso (65.3%), followed by $C_{16:0}$ 10-methyl (5.2%) and other iso-branched acids, such as $C_{16:1}$ iso H (4.6%), $C_{15:0}$ iso (3.4%), $C_{14:0}$ iso (3.2%), and $C_{15:0}$ iso2-OH (and/or $C_{16:1}$ ω7*c*) (3.2%). Components detected in lesser amounts (up to 2.5%) included mostly straight-chain monounsaturated and iso- and anteiso-branched fatty acids, as well as TBSA (0.5%) and $C_{17:0}$ 2-OH (0.7%). A mean DNA–DNA hybridization value of 33±9% was obtained to the type strain of *Nocardioides marinisabuli* (99.2% 16S rRNA gene sequence identity), with a lower DNA–DNA similarity (18 ± 6%) to more distant *Nocardioides kribbensis*. There are no data on the DNA–DNA similarity between *Nocardioides salarius* and the phylogenetically closest (99.6% 16S rRNA gene sequence similarity) species *Nocardioides basaltis* described by Kim et al. (2009a) shortly after the establishment of the species *Nocardioides salarius*). The type strains of these two species show many phenotypic features in common, including the fatty acid composition and physiological and biochemical traits. See the description of the species *Nocardioides basaltis* in this section, Table 215 and the original publications (Kim et al., 2008a, 2009a) for characteristics that might be helpful in distinguishing these two species. The type strain (and the only strain described) was isolated by enrichment culture (sea water supplemented with zooplankton incubated at 10–15°C for about 1 year) on low-nutrient heterotrophic medium (for details on the isolation procedure and the medium composition see Kim et al., 2008a; Cho and Giovannoni, 2004).

Source (type strain): sea water enriched with zooplankton, the South Sea, Korea.

DNA G+C content (mol%): 73.3 (HPLC).

Type strain: CL-Z59, KCCM 42320, DSM 18239.

Sequence accession no. (16S rRNA gene): DQ401092.

Additional remarks: the absence of data on the DNA–DNA similarity between *Nocardioides salarius* and the phylogenetically closest species *Nocardioides basaltis*, along with their very similar phenotypic traits suggest that further comparative taxonomic studies of these two species, are needed to support distinctions between these two species.

44. **Nocardioides sediminis** Dastager, Lee, Ju, Park and Kim 2009e, 281[VP]

se.di.mi′nis. L. gen. n. *sediminis* of a sediment, referring to the source from which the type strain was isolated.

Characteristics are as described for the genus and listed in Table 215. Information presented below is taken from the original species description (Dastager et al., 2009e).

Cells are mostly slender irregular rods (0.3–0.4 × 0.9–1.4 µm) after 3–5 d incubation on R2A agar (Difco) at 28°C. Non-separated coccoid cells and larger club-shaped and spherical forms up to 0.8 µm in diameter may occur. The cells from two-fold diluted R2A agar appeared to be motile under light microscopy but no flagella were detected. Colonies are translucent, cream–whitish, and slightly raised on R2A agar after 2 d growth at 28°C. Nutritionally non-exacting; grows on a mineral salts medium (ISP 9) with glucose as the carbon-plus-energy source and an ammonium salt as the sole nitrogen source. Growth also occurs with turanose but not with adonitol, adipate, D-arabitol, esculin, arbutin, dulcitol, erythritol, D-fucose, gentiobiose, gluconate, glycogen, D-lyxose, malate, sorbose, sorbitol, xylitol, or L-xylose tested under the same experimental conditions. Acid production from carbohydrates is rather uncommon or weak; no acid was formed from any of the tested carbon sources. The predominant fatty acids determined for cell mass harvested from R2A plates after incubation at 28°C for 7 d included $C_{16:0}$ iso (48.3%), $C_{17:1}$ ω8*c* (17.1%), $C_{17:0}$ iso (7%), $C_{17:0}$ 10-methyl (4.8%), and $C_{18:1}$ ω9*c* (4.3%). DNA–DNA

liter), and neutralized by K_2HPO_4.

similarity of the two type strains of the species *Nocardioides sedimentis* and *Nocardioides terrigena* was reported to be 34%. The type strain (the only strain described) was isolated using standard dilution techniques on tenfold-diluted R2A at 28°C.

Source (type strain): sediment sample taken at a depth of 60–70 m, Bigeum Island, Jeollanam-do Province, South Korea.

DNA G+C content (mol%): 71.5 (HPLC).

Type strain: MSL-01, DSM 19263, KCTC 19271.

Sequence accession no. (16S rRNA gene): EF466110.

45. **Nocardioides simplex** (Jensen 1934) O'Donnell, Goodfellow and Minnikin 1983, 896[VP] (Effective publication: O'Donnell, Goodfellow and Minnikin 1982, 327.) [*Pimelobacter simplex* (Jensen 1934) Suzuki and Komagata 1983b, 673[VP]; effective publication: Suzuki and Komagata 1983c, 69; *Arthrobacter simplex* (Jensen) Lochhead 1957, 608[AL]; "*Corynebacterium simplex*" Jensen, 1934, 43.]

sim′plex. L. masc. adj. *simplex* simple.

Characteristics are as described for the genus and listed in Table 215, Table 218, Table 219, and Table 221. Additional data are from O'Donnell et al. (1982), Suzuki and Komagata (1983c), and Keddie et al. (1986), unless indicated.

Cells are typically slender irregular rods, exhibiting a rod-to-coccus morphogenesis during the growth cycle. Irregular rods (~0.4–0.5 × 1.0–3.0 µm or longer) in late lag and exponential phase cultures and coccoid cells or very short rods (~0.4–0.5 µm in diameter) in older cultures were reported for the type strain on complex media by O'Donnell et al. (1982). Slightly wider cells (~0.5–0.9 µm in diameter), both in young and older cultures, were reported for this species by Keddie et al. (1986). Rods are typically motile with single- or peritrichous flagella. Colonies on yeast-peptone agar and most ISP media usually show no distinctive pigmentation. On YM agar and some other rich media, they may be slightly yellowish white or ivory in color, particularly in older cultures. A light brownish soluble pigment may occur in older cultures on some peptone-based media. Optimum growth temperature is ~26–30°C; grows at 10°C, and may or may not grow at 37°C. The type strain grows well in 5% NaCl but not in 7% NaCl (Nesterenko et al., 1985b).

Nutritionally non-exacting; grows in a suitable mineral salts medium with glucose as sole carbon-plus-energy source and an ammonium salt or nitrate as sole nitrogen source (Keddie et al., 1966; Owens and Keddie, 1969). The organism utilized about 60 out of the 180 compounds tested as sole or principal sources of carbon and energy. These include a very narrow range of carbohydrates and sugar derivatives, a wide range of fatty acids, simple alcohols, and amino acids, including some hydroxy-acids, oxo-acids, amines, pyrimidines, and other compounds (Keddie, 1974). The type strain utilizes acetate, citrate, succinate, fumarate, acetamide, L-asparagine, L-arginine, L-ornithine (Yi and Chun, 2004b, a), azelate, malonate, L-proline, histamine, thymine, uracil, and tetradecane (Collins et al., 1994) as sole carbon and energy sources, and tartrate in conventional tests. Negative results were recorded for utilization of L-lysine, benzoate, and hippurate(Yi and Chun, 2004b, a). Among carbohydrates tested by Yi and Chun (2004a), only D-glucose and sucrose supported growth. In the API 20NE or API 50 CH test system (AUX as suspending medium), the type strain utilized a few carbon sources for growth and energy, such as D-glucose, sucrose, trehalose, gluconate, adipate, and malate but not many other substrates, including D- and L-arabinose, D-cellobiose, D-fructose, D- and L-fucose, D-galactose, gentiobiose, D-lactose, D-melibiose, D-lyxose, D-maltose, D-mannose, D-melezitose, D-raffinose, L-rhamnose, D-ribose, D-tagatose, D-turanose, D- and L-xylose, D-sorbose, D- and L-adonitol, D- and L-arabitol, dulcitol, erythritol, glycerol, inositol, D-mannitol, D-sorbitol, xylitol, methyl α-D-mannoside, methyl α-D-glucoside, methyl β-D-xyloside, *N*-acetylglucosamine, amygdalin, arbutin, esculin, D-salicin, inulin, starch, glycogen, 2- and 5-ketogluconate, caprate, and phenylacetate (Kubota et al., 2005b; Yoon et al., 2009). Cui et al. (2009) reported the ability of the type strain to grow with L-alanine, L-histidine, L-serine, lactate, caprate, 3- and 4-hydroxybenzoic acids, 3-hydroxybutyrate, malic acid, propionate, suberate, and valerate (on mineral salts medium supplemented with vitamins and element solution); the strain in addition was reported to grow with maltose, D-mannose, melibiose, D-mannitol, salicin, *N*-acetylglucosamine as carbon and energy sources under the same experimental condition.

No acid is produced from glucose or other sugars by oxidation in peptone-based media in conventional tests (Keddie et al., 1986). No acid is produced from glucose and other sugars by the type strain using the API 20NE and API 50 CH test systems (Kubota et al., 2005a; Yi and Chun, 2004a). As mentioned before, the *Nocardioides simplex* strains transform sterols and their derivates (Arima et al., 1969; Nagasawa et al., 1969). They also were reported to utilize phenol as a sole carbon and energy source (Collins et al., 1994; Keddie et al., 1986), but the type strain could not grow in the presence of phenol at a concentration of 125 p.p.m. (Cui et al., 2009). The authors also found that this strain utilized dibenzofuran at 50 p.p.m. in the test medium (higher concentrations were growth-inhibiting) (Cui et al., 2009). According to Kubota et al. (2005a), the type strain *Nocardioides simplex* JCM 1363 did not use biphenyl and dibenzofuran as a carbon and energy source, in contrast to *Nocardioides aromaticivorans*. Five tested strains of *Nocardioides simplex*, in contrast to closely related species, were also unable to utilize *p*-nitrophenol as the sole carbon and energy source (Cui et al., 2009; Yoon et al., 1999) (Table 218).

The cell-wall peptidoglycan is of the A3γ type (LL-A_2pm-glycine) (Schleifer and Kandler, 1972). The well-documented cell-wall sugar is galactose (Keddie and Cure, 1977; Sadikov et al., 1983; Takeuchi and Yokota, 1989). In addition, the presence of glucose (Takeuchi and Yokota, 1989) or rhamnose (Sadikov et al., 1983) was reported for the type strain, and mannose for strain NBRC (IFO) 12679 = JCM 1366 (Takeuchi and Yokota, 1989). (Relationship to *Nocardioides simplex* was supported by DNA–DNA hybridization experiments; Suzuki and Komagata, 1983c; Yoon et al., 1999.) The wall polysaccharides of both the above strains were also found to contain a small or trace amount of glucosamine (Takeuchi and Yokota, 1989). Both strains had cell walls containing glycerol teichoic acids (Sadikov et al., 1983; Takeuchi and Yokota, 1989). The polyamine composition of the type strain, DSM 43109, harvested from rich (R) medium (Yamada and Komagata, 1972) was cadaverine

(56.6%), spermidine (18.6%), putrescine (15.0%), spermine (5.6%), and 1,3-diaminopropane (4.2%), with a trace amount of *sym*-homospermidine (Busse and Schumann, 1999). The predominant isoprenoid quinone is MK-8(H_4); minor quantities of MK-7(H_4), MK-8, MK-8(H_6), and a trace amount of MK-9(H_4) may be detected (Collins et al., 1979; Collins et al., 1983; O'Donnell et al., 1982; Suzuki and Komagata, 1983c; Yamada et al., 1976).

The fatty acids of *Nocardioides simplex* to a large extent depends on the culture conditions and analytical procedures (Collins et al., 1983; Cui et al., 2009; Miller et al., 1991; O'Donnell et al., 1982; Schumann et al., 1997; Suzuki and Komagata, 1983c; Yoon et al., 1999; Yoon et al., 1997a). When strains of this and other species of this genus are analyzed under similar experimental conditions, the fatty acid profiles of *Nocardioides simplex* are very similar (Yoon et al., 1999) and differ from those of other species (Cui et al., 2009; Yoon et al., 1999), including closely related ones (Table 219). The cellular fatty acids (4% or more), determined for 5 strains grown on nutrient agar (NA; Difco) for 4 d at 30°C were $C_{16:0}$ iso (29.0–36.6%), $C_{18:1}$ ω9*c* (7.3–12.0%), $C_{17:1}$ ω6*c* (11.9–14.8%), TBSA (9.3–15.3%), $C_{17:0}$ 10-methyl (2.4–6.3%), $C_{16:0}$ 10-methyl (1.1–4.2%), $C_{16:1}$ iso H (2.8–6.6%), and $C_{17:0}$ iso (2.2–6.4%). The cells of the type strain grown in trypticase soy broth (Difco) for 24–48 h at 28°C contained different proportions of predominant fatty acids: $C_{16:0}$ iso (41.8%), $C_{18:1}$ (13.1%), $C_{17:1}$ (5.2%), TBSA (5.2%), $C_{16:1}$ (5.0%), $C_{14:0}$ iso (4.6%), and also had a lower level of 10-methyl-branched components (Schumann et al., 1997). The presence of 2-hydroxylated acids was also detected (Collins et al., 1983; Suzuki and Komagata, 1983c; Yoon et al., 1999), which may contribute up to 10% in some experiments (Suzuki and Komagata, 1983c). The phospholipids also varied between different studies and included diphosphatidylglycerol, phosphatidylglycerol, and a few incompletely characterized components (Collins et al., 1989; Collins et al., 1983; O'Donnell et al., 1982). The presence of phosphatidylglycerol with a significant amount of 2-hydroxy fatty acids at the 2-position was reported by Yano et al. (1970, 1971). There is also a report about tentative identification of substantial proportions of phosphatidylinositol mannosides and phosphatidylethanolamine in *Arthrobacter simplex* ("*Corynebacterium*" *simplex*) grown on *n*-alkanes (Yanagawa et al., 1972). In our recent experiment, only three clearly dominating phospholipids were detected for the type strain of *Nocardioides simplex*, namely, phosphatidylglycerol and two similar unidentified phospholipids, one of which was found to include inositol and is most likely phosphatidylinositol, while the second is supposedly phosphatidylinositol containing a hydroxy acid (Figure 263).

Nocardioides simplex is susceptible to some actinophages among those multiplying on mycelium-forming *Nocardioides* strains (Prauser, 1976, 1981, 1989).

Strains affiliated with this species had 60–100% DNA–DNA similarity (using the membrane filter method with tritium-labeled DNA; Suzuki and Komagata, 1983c) and more than 85% (Yoon et al., 1999, using the method of Ezaki et al., 1989). The levels of DNA–DNA hybridization between the type strain of *Nocardioides simplex* and type strains of the species composing the tight *Nocardioides simplex* phylogenetic group were reported to be 13–55% (Cui et al., 2009; Kubota et al., 2005a; Yoon et al., 1999, 2006b, 2009; Table 221). The DNA–DNA hybridization values of the type strain of *Nocardioides simplex* with those of the type strains of more distant species (*Nocardioides plantarum*, *Nocardioides albus*, *Nocardioides luteus*, and *Nocardioides jensenii*) obtained by the method of Ezaki et al. (1989) were reported to be 28–33% (Kubota et al., 2005a). A lower DNA–DNA binding level (16–22%) was found between members of *Nocardioides simplex* and the type strains of *Nocardioides albus* and *Nocardioides jensenii* (using the membrane filter method; Suzuki and Komagata, 1983c). Similar values (15–20%) were reported for *Nocardioides simplex* and mycelium-forming strains of *Nocardioides* by Prauser (1981). Strains of *Nocardioides simplex* are very similar in the length and nucleotide sequences of the 16S–23S ITS region and clearly distinguished from *Nocardioides nitrophenolicus* and other members of this genus by these characteristics (Yoon et al., 1998a). The type strains of *Nocardioides simplex* and other species included in the study are also different in the RNase P RNA gene sequences (Yoon and Park, 2000).

Selected phenotypic characteristics useful in distinguishing *Nocardioides simplex* from phylogenetically closely related species are listed in Table 218. Occur mostly in soil. The type strain was isolated as described by Jensen (1934).

Source (type strain): rice soli.

DNA G+C content (mol%): 71.7–73.5 (HPLC, T_m); 71.7 (HPLC) for the type strain.

Type strain: AJ 1420, ATCC 6946, CCM 1652, CCUG 23611, CIP 82.106, DSM 20130, HAMBI 90, HAMBI 1861, IAM 1660, IFO (now NBRC) 12069, JCM 1363, KCTC 9106, LMG 16261, NRRL B-14051, NRRL B-3157, VKM Ac-1118.

Sequence accession no. (16S rRNA gene): X53213, AF005009.

Additional remarks: first described as "*Corynebacterium simplex*" (Jensen, 1934), this species was then affiliated to the genus *Arthrobacter* as *Arthrobacter simplex* (Lochhead, 1957) and later reclassified, mainly on chemotaxonomic grounds, as *Nocardioides simplex* (O'Donnell et al., 1982, 1983). Independently, Suzuki and Komagata (1983b, 1983c) established the genus *Pimelobacter* to accommodate *Arthrobacter simplex* and some related organisms. Those, in particular, included two strains (IAM 1398 = IFO 1366 and IAM 1413 = IFO 1367) isolated from soils of an oilfield in Japan and originally described as "*Brevibacterium lipolyticum*" (Iizuka and Komagata, 1964). Strain NCIB 9770, originally identified as *Arthrobacter simplex* (Jensen and Gundersen, 1956) was reclassified as a representative of a novel species of the genus *Pimelobacter*, *Pimelobacter jensenii* (Suzuki and Komagata, 1983b, 1983c), and subsequently transferred to *Nocardioides* as *Nocardioides jensenii* (Collins et al., 1989). Some other strains (ATCC 13260, 19565, and 19566) originally described under the name *Nocardioides simplex* were reidentified as members of the genus *Rhodococcus* (Yoon et al., 1997a). Notably, other strains cited in the literature under the species name *Nocardioides simplex* might also not belong to this species, particularly in light of recent proposals regarding some species phylogenetically closely related to *Nocardioides simplex* (Table 218). Although some of these strains (e.g. *Nocardioides simplex* VKM Ac-2033D involved in transformation of sterols (Fokina et al., 2003a, 2003b) or *Nocardioides simplex* 3E involved in degradation of 2,4,5-trichlorophenoxyacetic acid (Golovleva et al., 1990)

exhibit a very high 16S rRNA gene sequence similarity to the type strain of *Nocardioides simplex*, their relationship to this species was not firmly supported by DNA–DNA hybridization or other relevant genotypic studies.

46. **Nocardioides terrae** Zhang, Liu and Liu 2009a, 2447[VP]

ter′ra.e. L. gen. n. *terrae* of or from the earth.

Characteristics are as described for the genus and listed in Table 215. Information presented below is based on the original species description (Zhang et al., 2009a).

Cells are slender irregular rods or coccoid. Data on the cell size are conflicting. In the species description, the cells are 0.2–0.3 µm in diameter and 0.3–1.0 µm long. As seen from the micrograph provided, most cells after 3 d in culture on R2A agar (30°C) appear as short rods, mostly about 0.3–0.5 µm in diameter and up to 1.0 µm long; longer cells, up to 2–2.3 µm may also occur. Coccoid cells of the same diameter, slightly smaller or increased are observable. The general appearance of the cells suggests the occurrence of a rod-to-coccoid growth cycle. Nonmotile, no flagella are observed. Colonies are cream-colored on R2A agar. Grows at 16–34°C (optimum, 29°C), but prefers not to grow at 14 or 36°C. Grows at pH 5.5–8.5 (optimum pH 6.2–6.5) and in 0–1% (w/v) NaCl (optimum 0–0.25%), as assessed in R2A broth. Along with substrates listed in Table 215, the organism assimilates gluconate as a carbon source, but not adipate, caprate, and citrate (API 20 NE). Acids are produced from D-glucose, L-rhamnose, and weakly from starch (API 50 CH). Acids are also formed from D-cellobiose, D-galactose, maltose, D-ribose, and trehalose (characteristics differentiating this species from the phylogenetically close species *Nocardioides panacihumi*). The type strain contains *N*-acetyl-β-glucosaminidase. Tween 20 is not hydrolyzed. Glucose fermentation (API 20NE) occurs. The major cellular fatty acids (>5% of the total) determined for cell mass scraped from R2A after incubation at 30°C for 3 d were $C_{16:0}$ iso (18.1%), TBSA (11.8%), $C_{17:0}$ 10-methyl (10.7%), $C_{17:1}$ ω8*c* (7.0%), $C_{15:0}$ iso (6.1%), $C_{18:1}$ ω9*c* (5.3%), and $C_{16:0}$ 10-methyl (5.1%). Levels of DNA–DNA similarity between the type strain of this species and the type strains of *Nocardioides panacihumi* and *Nocardioides marinus* were reported to be 21 and 16%, respectively (thermal denaturation method). The type strain (the only strain described) was isolated on VL55 medium (Sait et al., 2002) modified by adding 10 ml per liter of an amino acid mixture (Davis et al., 2005) and using gellan as a solidifying agent. The strain was isolated from a plate inoculated with the 10^{-7} dilution after 1 week of incubation at 30°C.

Source (type strain): forest soil, the Changbai Mountains, Heilongjiang Province, China.

DNA G+C content (mol%): 71.6 (T_m).

Type strain: VA15,CGMCC 1.7056, JCM 16799, NBRC 104259.

Sequence accession no. (16S rRNA gene): FJ423762.

47. **Nocardioides terrigena** Yoon, Kang, Lee and Oh 2007a, 2474[VP]

ter.ri.ge′na. L. masc. or fem. n. *terrigena* child of the earth, referring to the isolation of the type strain from soil.

Characteristics are as described for the genus and listed in Table 215. Additional information is from the original species description (Yoon et al., 2007a).

Cells are nonmotile rods or cocci (0.4–0.7 × 0.7–2.0 µm) in the exponential phase of growth. A rod–coccus morphogenetic growth cycle occurs during growth on complex media. Neither substrate nor aerial mycelium is formed. Gram-staining is variable in old cultures. Colonies are ivory in color and 1.0–1.2 mm in diameter after 7 d incubation on R2A agar at 30°C. Grows at 4 and 35°C, but prefers not to grow at 36°C. Grows in 0–3% but not at 4% (w/v) NaCl, with optimum growth at 0.5–1.0% (w/v) NaCl (assessed in R2A broth prepared according to the Difco formula without agar). Optimal pH for growth is around 8.0. Gentiobiose, D-lyxose (weak), D-turanose, adipate, gluconate and L-malate, but not D-arabinose, D- and L-fucose, sorbose, D-tagatose, L-xylose, D- and L-arabitol, erythritol, dulcitol, sorbitol, xylitol, caprate, 2- and 5-ketogluconate, phenylacetate, methyl β-D-xyloside, methyl α-D-mannoside, methyl α-D-glucoside, glycogen, esculin, amygdalin, and arbutin are utilized as sole carbon and energy sources. Tweens 20, 40, and 60 are hydrolyzed. The type strain is susceptible to the following antibiotics (µg per disk, unless indicated): ampicillin (10), carbenicillin (100), cephalothin (30), chloramphenicol (100), kanamycin (30), lincomycin (15), neomycin (30), novobiocin (5), oleandomycin (15), penicillin G (20 U), and streptomycin (50) and weakly susceptible to tetracycline (30); resistant to gentamicin (30) or polymyxin B (100 U). The main fatty acids included $C_{16:0}$ iso (35.5%), $C_{17:1}$ ω8*c* (30.2%), and $C_{17:0}$ (11.5%). Minor compounds reported were represented by various saturated, monounsaturated, iso-, anteiso- and 10-methyl-branched fatty acids characteristic of the genus *Nicardioides*, each contributing 0.8–2.7%. TBSA was not detected among fatty acids that exceeded 0.5%. The DNA–DNA hybridization value was 34% for the type strain *Nocardioides terrigena* and type strain of the most closely related species, *Nocardioides sediminis* (Dastager et al., 2009e), and 7% for the type strains of *Nocardioides terrigena* and *Nocardioides basaltis* (Kim et al., 2009a). The type strain (the only strain described) was isolated using the standard dilution plating technique on tenfold-diluted nutrient agar (Difco) at 25°C.

Source (type strain): soil, Dokdo, Korea (37°14′12″N; 131°52′07″E).

DNA G+C content (mol%): 71.5 (HPLC).

Type strain: DS-17, KCTC 19217, JCM 14582.

Sequence accession no. (16S rRNA gene): EF363712

48. **Nocardioides tritolerans** Dastager, Lee, Ju, Park and Kim 2009a, 1555[VP] (Effective publication: Dastager, Lee, Ju, Park and Kim 2008c, 1205.)

tri.to′le.rans L. pref. *tri-* (from L. num. adj. *tris*), three; L. part. adj. *tolerans* tolerating; N.L. part. adj. *tritolerans* referring to the ability of the organism referring to the ability of the organism to tolerate relatively high salinity, alkalinity and temperature.

Characteristics are as described for the genus and listed in Table 215. Information presented below is taken from the original work on species description (Dastager et al., 2008c).

Cells are typically motile irregular rods, mostly about 0.3–0.5 µm wide and up to 4.0 µm long on R2A medium. A week-old culture on the same medium is mostly composed of short rods, not exceeding 1 µm in length; a small fraction

of coccoid cells is present. Larger club-shaped or spherical forms, up to 1.4 µm in diameter may occur (Figure 257). Colonies are translucent, cream in color, slightly raised, and 0.9–1.3 mm in diameter after 4–5 d incubation on R2A medium at 30°C. Grows at 20–40°C, but not at 19°C or 41°C. Grows well on R2A medium at initial pH 6.0–11.0 (optimum, pH 7.0–7.5), with weak growth at pH 12, and on R2A medium containing up to 7.0% (w/v) NaCl.

Acids are produced from many sugars listed in Table 215, as tested by conventional methods. The fatty acids of cells harvested from R2A after incubation for 5 d at 28°C included $C_{16:0}$ iso (40.6%), $C_{17:1}$ ω8*c* (7.3%), $C_{18:1}$ ω9*c* (6.1%), $C_{17:1}$ (4.5%), $C_{15:0}$ iso (4.5%), $C_{17:0}$ anteiso (4.4%), $C_{17:0}$ iso (4.1%), $C_{17:0}$ 10-methyl (2.9%), $C_{17:1}$ ω6*c* (2.9%), $C_{17:1}$ iso ω9*c* (2.8%), $C_{16:1}$ iso (2.6%), and $C_{16:0}$ (2.4%); other acids reported were $C_{14:0}$ iso, $C_{18:0}$ iso, $C_{18:0}$, and $C_{15:1}$ anteiso, each contributing 1.4–1.8%. The type strain (and the only strain described) was isolated by serial dilution plating on tenfold-diluted R2A agar at 30°C after 7 d incubation.

Source (type strain): soil, Bigeum Island, Korea.

DNA G+C content (mol%): 67.6 (HPLC).

Type strain: MSL-14, KCTC 19289, DSM 19319.

Sequence accession no. (16S rRNA gene): EF466107.

Genus II. **Actinopolymorpha** Wang, Zhang, Xu, Ruan and Wang 2001, 472[VP]

Lyudmila I. Evtushenko

Ac.ti.no.po.ly.mor'pha. Gr.n. *actis*, *actinos* a ray; Gr. adj. *polumorphos* multiform, manifold; N.L. fem. n. (N.L. fem. adj. used as a substantive) *Actinopolymorpha* actinomycete of many shapes.

Branched fragmenting vegetative hyphae of uneven thickness to highly pleomorphic cells of different sizes, both usually **growing on the agar surface**. Marked **apical and lateral budding** is often observable. Cells may remain attached after division, forming **short chains and small aggregates**. Colonies are white, yellow, or orange in color, mostly of a pasty consistency, smooth, or wrinkled. Scant or moderate aerial mycelium occasionally occurs in older cultures on some media. Endospores are not formed. Nonmotile. Gram-stain-positive. Non-acid-fast. **Chemo-organotrophic with a respiratory type of metabolism.** Catalase- and oxidase positive. Grow aerobically on standard laboratory media, including the chemically defined (synthetic) media. Oxidative acid production from glucose and some other carbohydrates. Mesophilic (optimum temperature ~28°C), non-salt-requiring. Diagnostic diamino acid of the cell wall is **LL-diaminopimelic acid**. Menaquinones are the sole respiratory quinones detected; the major component is tetrahydrogenated or hexahydrogenated menaquinone with nine isoprene units, **MK-9(H_4) or MK-9(H_6)**. The fatty acid profile dominated by **iso-branched acids ($C_{16:0}$ iso, $C_{15:0}$ iso, $C_{17:0}$ iso, and $C_{16:1}$)**; anteiso-branched, hydroxylated, and 10-methyl branched fatty acids usually contribute lesser or minor amounts. Polar lipid pattern includes **phosphatidylinositol mannosides, phosphatidylinositol, diphosphatidylglycerol, and phosphatidylglycerol.** The described *Actinopolymorpha* species have been isolated from soil or plant tissues.

DNA G+C content (mol%): 66.6–69.6.

Type species: **Actinopolymorpha singaporensis** Wang, Zhang, Xu, Ruan and Wang 2001, 472[VP].

Further descriptive information

Based on the 16S rRNA gene sequence analysis, the genus *Actinopolymorpha* represents, together with the recently described genera *Thermasporomyces* (Yabe et al., 2011) and *Flindersiella* (Kaewkla and Franco, 2010a), a separate subcluster within the family *Nocardioidaceae*, order *Propionibacteriales* (formerly suborder *Propionibacterineae* Stackebrandt et al. 1997) (see Figure 247). The genus currently includes five species: the type species *Actinopolymorpha singaporensis* (Wang et al., 2001), *Actinopolymorpha rutila* (Wang et al., 2008b), *Actinopolymorpha alba* (Cao et al., 2009), *Actinopolymorpha cephalotaxi* (Yuan et al., 2010), and *Actinopolymorpha pittospori* (Kaewkla and Franco, 2010a). The information given below is from the original species descriptions, unless indicated.

All organisms, when cultured on agar media, grow on the agar surface, and occasionally weakly penetrate it (reported for *Actinopolymorpha singaporensis*). The colonies are pasty, usually smooth at first and later wrinkled. A marked morphological differentiation within colonies may be observable (Figure 264). The colony color varies depending on species and growth medium, and usually is white or yellow to orange of different intensity and shade (see Table 222 and the species description for more details). Aerial mycelia white in color may develop in older cultures on certain agar media (Table 222), which is mostly scant but may be moderate to good, e.g. mycelia of *Actinopolymorpha*

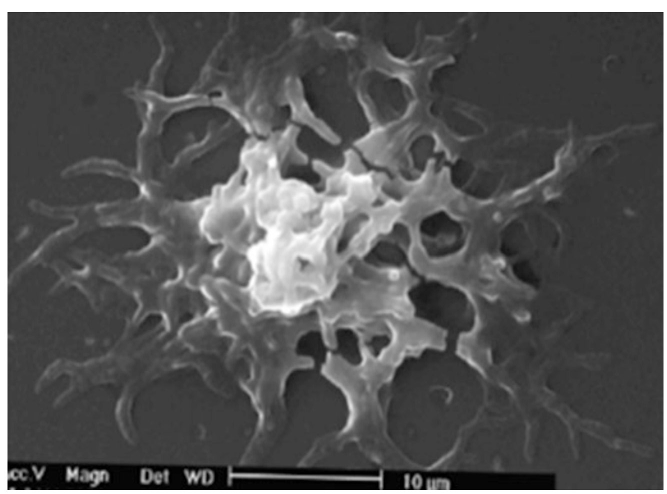

FIGURE 264. Scanning electron micrograph of a microcolony of *Actinopolymorpha rutila* YIM 45725 grown on ISP 2 agar at 28°C for 12 d. (Reproduced with permission from Wang et al., 2008b. Int. J. Syst. Evol. Microbiol. *58*: 2443–2446.)

TABLE 222. (continued)

Characteristic	*A. singaporensis*	*A. alba*	*A. cephalotaxi*	*A. pittospori*	*A. rutila*
Source of type strain	Soil, primary rain-forest	Soil, plant rhizo-sphere	Soil, rhizosphere of Chinese cowtail pine (*Cephalotaxus fortunei*)	Leaves of apricot tree (*Pittosporum phylliaeoides*)	Soil, forest

[a]Based on characteristics of type strains. Data from Wang et al. (2008b, 2001), Cao et al. (2009), Yuan et al. (2010), and Kaewkla and Franco (2010b, 2010a). Symbols and abbreviations: +, positive; –, negative; v, variable between experiments or test methods; w, weak; LL-A_2pm, 2,6-diaminopimelic acid; Glc, glucose; Gal, galactose; Rib, ribose; Rha, rhamnose; HPDA, half-strength potato dextrose agar (Atlas, 1993); BA, Bennett's agar (Atlas, 1993); NA, nutrient agar (Atlas, 1993); TSB, tryptic soy broth (Difco); nd, not determined.

[b]Tested on ISP 2 agar, except *Actinopolymorpha alba* examined on TSA [3% (w/v) trypticase soy broth (BBL); 1.5% (w/v) Bacto agar (Difco)] (data from the original species descriptions and Kaewkla and Franco, (2010a, 2010b).

[c]Conflicting test results were reported by Kaewkla and Franco (2010b, 2010a).

[d]Lower NaCl concentrations allowing growth of *Actinopolymorpha singaporensis* (3%), *Actinopolymorpha alba* (1%), and *Actinopolymorpha rutila* (3%) were obtained using basal medium ISP 2 at 27°C (Kaewkla and Franco, 2010a, 2010b).

[e]Tested on basal medium ISP 9 (data from the original species descriptions, and from Kaewkla and Franco, 2010b).

[f]According to the method of Gordon et al. (1974).

[g]Predominant menaquinone and components detected in lesser amounts (in parenthesis); numerals indicate the numbers of isoprene units and the number of hydrogen atoms on the side chain (e.g. 9/4 is partially saturated chain with 4 hydrogen atoms on the side chain containing 9 isoprene units).

[h]Obtained using the standard protocol of the MIDI System in cells cultured under different conditions. Data for cells grown in liquid Tryptic Soya Broth medium, TSB (Oxoid) at 27°C for 10 d (Kaewkla and Franco, 2010b) are given in bold; data for cells grown at 28°C for 6 d in liquid TSB (Difco) (Yuan et al., 2010) are underlined; data for *Actinopolymorpha rutila* (Wang et al., 2008b) and *Actinopolymorpha alba* (Cao et al., 2009) cells cultured for 5 d at 28°C on TSA agar [3% trypticase soy broth (BBL) and 1.5% Bacto agar (Difco)] are presented neither in bold nor underlined.

[i]Other diagnostic fatty acids detectable irregularly in minor (< 5%) or trace amounts, except $C_{14:0}$ iso 3-OH (which is reported to constitute 11.8% in 5-d cultures of *Actinopolymorpha alba* grown at 28°C on TSA agar (Cao et al., 2009).

pittospori grown on half-strength potato dextrose agar (HPDA; Atlas, 1993).

Various morphological forms, extending from well developed branched hyphae with swollen hyphal segments to highly pleomorphic cells (irregularly-sized globular, coccoid, rod-shaped, and angular), which are often produced by apical and lateral budding, is a characteristic feature of organisms of this genus (Figure 265, Figure 266, and Figure 267). The observable morphologies depend on species, growth medium, the culture age, and location in colonies. The cells produced by budding often remain attached after division, forming aggregates and short chains (pseudomycelium). The cells in chains resemble at maturation exospores (arthrospores) of spore-forming actinomycetes (Figure 265c). The cells may give rise to new buds which further develop into cells of different shapes or hyphae as growth proceeds or when a culture is transferred to fresh medium. The marked hyphal elongation by budding was emphasized for *Actinopolymorpha singaporensis* (which has been described in more morphological detail) at a later growth stage (Figure 265c), but probably takes place in some other species of this genus. No data are available on the fine structure of thickened hyphae, hyphal swellings or globular forms (presumably cell clusters) examined by electron microscopy of thin sections. There are certain analogues of images of such morphological structures with those observed, e.g. in strains of *Kribbella* (chapter in this volume), *Friedmanniella* (Schumann et al., 1997), and, especially, *Pseudonocardia* which, in addition, are characterized by the growth of hyphae by budding (Agre et al., 1984; Evtushenko et al., 1989; Henssen et al., 1983; Kuimova and Malishkaite, 1984). Likewise with these genera, it might be suggested that the cells composing clusters or thickened hyphal masses may divide internally by differently oriented septa. Members of *Actinopolymorpha* were reported not to produce "classical" sporangia typical of sporangial actinomycetes (e.g. *Actinoplanes*). However, it cannot be excluded that the aforementioned cell clusters (subclusters) may have a common envelope (to be designated as "sporangia"?).

Gram-stain-positive. Non-acid and non-alcohol-fast (examined for *Actinopolymorpha pittospori*). The cell wall contains LL-diaminopimelic acid (LL-A_2pm), as reported for all species; no data on the other peptidoglycan amino acids are available. The whole-cell sugars detected include glucose, galactose, rhamnose, and ribose in different combinations (Table 222). The menaquinone systems contain MK-9(H_6) as the predominant compound for *Actinopolymorpha singaporensis* and *Actinopolymorpha alba*, or MK-9(H_4) for the remaining species. Additional menaquinones, i.e. MK-9(H_8), MK-10(H_4), MK-10(H_6), and MK-10(H_8) in different combinations have been found in lesser or minor amounts (Table 222). Some shifts in the predominant menaquinone and the menaquinone patterns in this genus may be influenced by the medium composition and the age (developmental stage) of cultures, as suggested from some examples with other actinomycetes (Li et al., 2003; Saddler et al., 1986; Tanaka et al., 1996). All species contain similar patterns of principal polar lipids, i.e. phosphatidylinositol mannosides, phosphatidylinositol, diphosphatidylglycerol, and phosphatidylglycerol. An exception is *Actinopolymorpha cephalotaxi* which has been reported to lack diphosphatidylglycerol; no data are available for *Actinopolymorpha pittospori.* The fatty acid profiles are dominated by iso-branched components, mostly $C_{16:0}$ iso, $C_{15:0}$ iso, $C_{17:0}$ iso, and $C_{16:1}$ iso (Table 222). In addition, anteiso-branched and hydroxylated acids may be detected in significant proportions for certain species in some experiments. 10-Methyl-branched acids ($C_{16:0}$ 10-methyl and $C_{17:0}$ 10-methyl) are usually

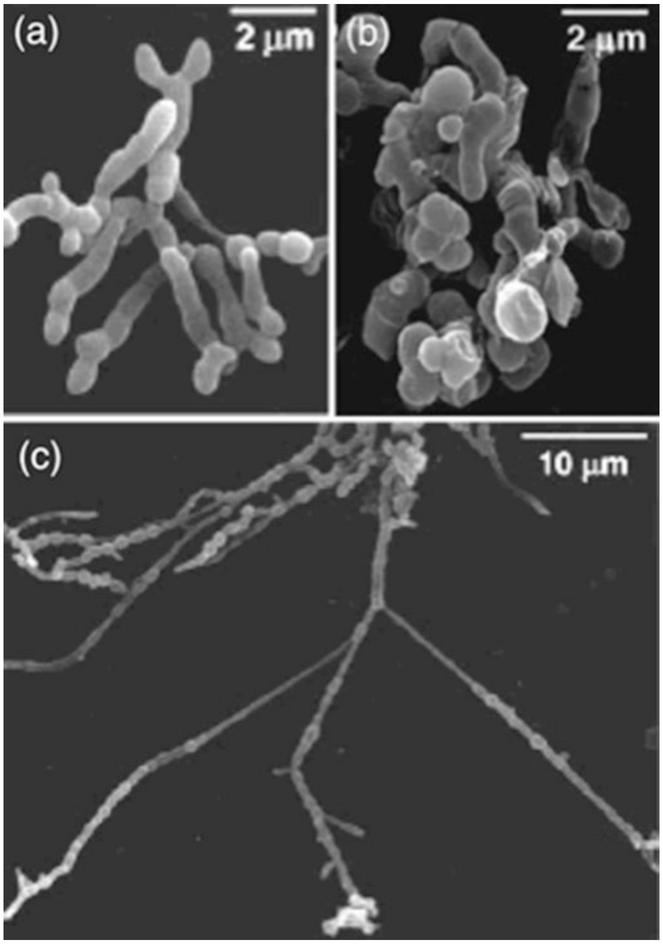

FIGURE 265. Cellular morphology of *Actinopolymorpha singaporensis*. Scanning electron micrographs of cells of strain *Actinopolymorpha singaporensis* IM 7744 grown on ISP 4 (a) and ISP 3 (b) media for 8 d; hyphae at the periphery of a colony on ISP 3 medium in 35-d-old culture (c). (Reproduced with permission from Wang et al., 2001. Int. J. Syst. Evol. Microbiol. *51*: 467–473.)

present but not in excess of 5%. The patterns of predominant fatty acids (and the fatty acid profiles as a whole) vary with species and the culture age (developmental stage). The most common change for cultures grown on trypticase soy broth (agar) is that the proportions of saturated iso-branched acids increase in older (10 d) cultures compared with younger (5–6 d) cultures, while that of unsaturated ($C_{16:1}$ iso) decreases (Table 222).

All species grow aerobically on complex agar media at nearly neutral pH at ~28°C and also are capable of growing on chemically defined ISP* media, including minimal salts medium ISP 9 supplemented with glucose or some other carbon sources. Some species were reported to grow on inorganic salt-starch agar (ISP 4) and Czapek's agar (Pridham and Lyons, 1980). The species differ in the rate and abundance of growth, but all form colonies within 8–10 d at 27–28°C on yeast extract-malt extract agar (ISP 2) and some other media.

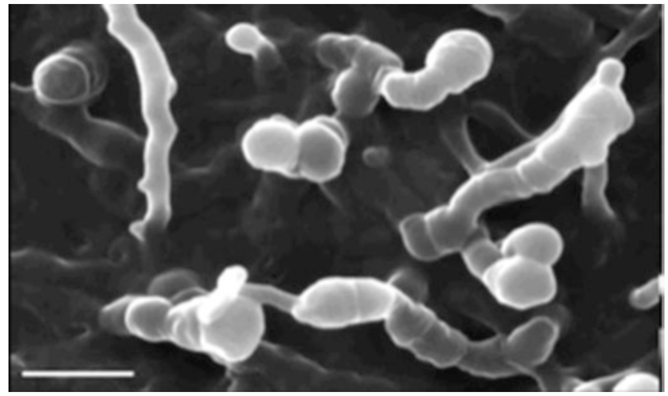

FIGURE 266. Cellular morphology of *Actinopolymorpha alba*. Scanning electron micrograph of cells of strain *Actinopolymorpha alba* YIM 48868 grown on ISP 2 agar for 12 d at 28°C. Bar = 2 µm. (Reproduced with permission from Cao et al., 2009. Int. J. Syst. Evol. Microbiol. *59*: 2200–2203.)

All species produce acid during aerobic growth from glucose and other carbohydrates (Table 222). All tested strains exhibit positive reactions for catalase and oxidase (no data on oxidase for *Actinopolymorpha pittospori*). Nitrate reduction varies with species (Table 222). All tested strains hydrolyze gelatin, but show negative results in the classical tests for hydrolysis of cellulose or starch (no data on *Actinopolymorpha pittospori*). *Actinopolymorpha singaporensis* and *Actinopolymorpha rutila* so far examined test positive for hydrolysis of casein, Tween 20, but negative for decomposition of Tween 80, and adenine. The four species (*Actinopolymorpha alba*, *Actinopolymorpha cephalotaxi*, *Actinopolymorpha rutila*, and *Actinopolymorpha singaporensis*) so far tested with the API ZYM system exhibit various enzymatic activities (see the species descriptions for details). The optimal growth temperature is ~28°C, some species can grow at 37°C or somewhat higher temperatures in appropriate conditions (Table 222). The recognized *Actinopolymorpha* species are non-salt-requiring, but some may tolerate up to 7% NaCl (e.g. *Actinopolymorpha alba* when tested on ISP 2 medium at 28°C; Cao et al., 2009), or even 15% (weak growth was reported for *Actinopolymorpha singaporensis* in liquid TSB as basal medium; Wang et al., 2001). A lower salt resistance of the above species and also *Actinopolymorpha rutila* was observed by Kaewkla and Franco (2010a, 2010b) on ISP 2 as basal medium at a slightly lower temperature (27°C). Organisms of this genus are considered to be neutrophilic, grow best at pH 6–8. They also may show growth at initial pH 6 and 10 on ISP 2 medium; some can grow at pH 5 (Kaewkla and Franco, 2010a, 2010b).

The DNA base ratio is 66.6–69.6 mol% (Table 222). The 16S rRNA gene sequence similarity ranges from 97.5% (the pair *Actinopolymorpha alba*–*Actinopolymorpha pittospori*) to 99.5% (*Actinopolymorpha cephalotaxi*–*Actinopolymorpha rutila*). The DNA–DNA similarity between the phylogenetically closest species obtained by the thermal denaturation method was 33.8% (Yuan et al., 2010). The highest value of DNA–DNA similarity (53.1%) was reported (Cao et al., 2009) for the pair *Actinopolymorpha alba*–*Actinopolymorpha rutila*, obtained by using the modified (Christensen et al., 2000) fluorometric micro-well method of Ezaki et al. (1989).

* Mineral salts medium: 11.8 g of NaCl, 0.32 g of KC1, 2.26 g of MgCl2·6H_2O, 2.97 g of $MgSO_4$·7H_2O, 0.65 g of $CaCl_2$·2H_2O, 0.2 g of $NaNO_3$, 0.2 g of NH_4C1 in 1 liter

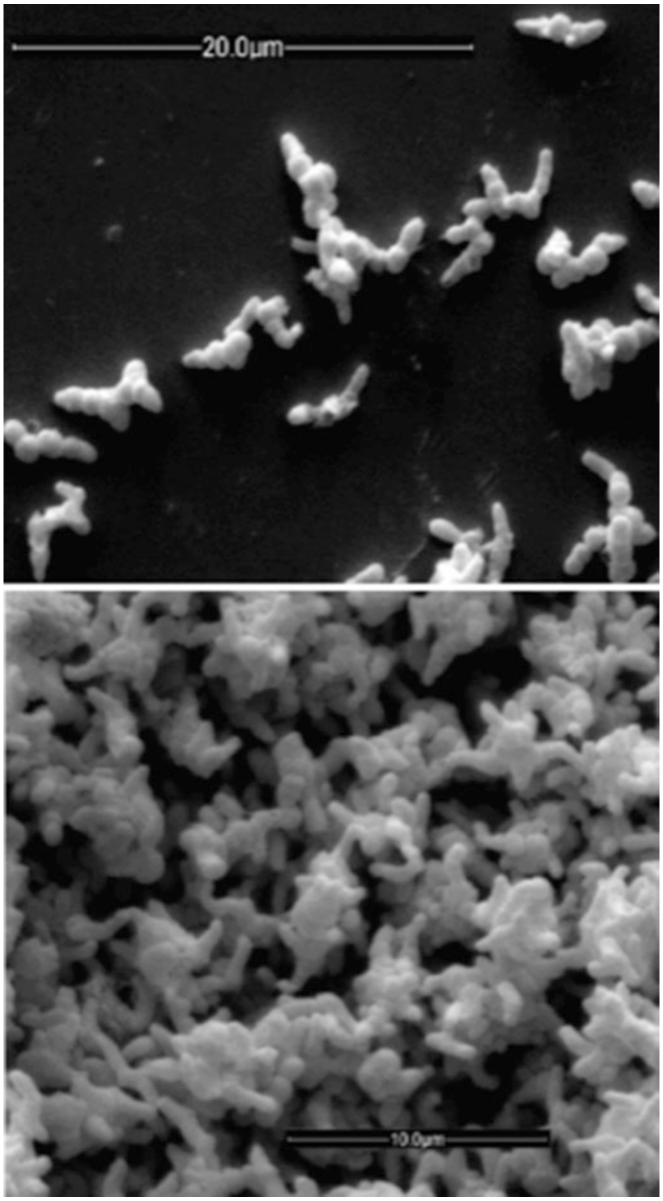

FIGURE 267. Cellular morphology of *Actinopolymorpha cephalotaxi*. Scanning electron micrographs of strain *Actinopolymorpha cephalotaxi* I06-2230 grown on ISP 2 agar for 14 d at 28°C. (Reproduced with permission from Yuan et al., 2010. Int. J. Syst. Evol. Microbiol. *60:* 51–54.)

All species are sensitive to 0.1% phenol. The sensitivity to antibiotics has not been tested directly, but it may be assumed from the composition of the isolation media that *Actinopolymorpha cephalotaxi* resists aztreonam (25 mg/l), while *Actinopolymorpha pittospori* tolerates nalidixic acid (20 µg/ml). *Actinopolymorpha singaporensis* may be resistant to penicillin or streptomycin, or both (the isolation procedure included pre-incubation of a soil sample in LB medium containing both these antibiotics, each 10 µg/ml). *Actinopolymorpha rutilus* YIM 45725 produces an estrogenic ligand, actinopolymorphol A, that preferentially induces heterodimerization of estrogen receptors ERα and ERβ and modulate estrogen receptor function (Huang et al., 2010; Powell et al., 2010).

Knowledge of the natural habitat of *Actinopolymorpha* species is fragmentary. A few available strains of this genus were isolated from forest soils or plant rhizosphere. An endophytic species, *Actinopolymorpha pittospori*, inhabited leaves of the Australian native apricot tree, *Pittosporum phylliraeoides*. Notably, members of *Actinopolymorpha* have not been reported so far in numerous ecological studies performed by direct non-culture (metagenomic) methods, in contrast to vast diversity of other organisms (clones) of the family *Nocardioidaceae*. No data have been reported on the possible pathogenic properties.

Enrichment and isolation procedures

Several strains of this genus have been isolated by plating on suitable agar media and incubation at 27–30°C for 3–11 weeks. The isolation media were yeast extract–malt extract agar (ISP 2), oatmeal agar (ISP 3) used for isolation of *Actinopolymorpha singaporensis*, inorganic salt-starch agar (Gauze 1; Gauze et al., 1983) for *Actinopolymorpha alba*, and starch-glycerol-proline agar with aztreonam (25 mg/l) for *Actinopolymorpha cephalotaxi*. A complex medium VL70 containing a mixture of 17 amino acids and solidified with 0.8% gellan gum (Hudson et al., 1989; Schoenborn et al., 2004) and supplemented with nalidixic acid and nystatin (each 20 µg/ml) was used to isolate *Actinopolymorpha pittospori* from the surface-sterilized and crushed leaves of *Pittosporum phylliraeoides*. The sterilization procedure included treatment with 70% ethanol and 6% hypochlorite (for 5 min each), followed by repeated rinsing with sterile water, treatment with 10% $NaHCO_3$ (10 min), and final rinsing with sterile water. Seeded plates were kept for 11 weeks until isolation in plastic sealed boxes, which contained wet paper towels to maintain humidity. To isolate *Actinopolymorpha singaporensis*, a soil sample was pre-incubated in Luria–Bertani (LB) medium containing penicillin and streptomycin (each 10 µg/ml), which eliminated many fast-growing bacteria. The soil sample was first dried in a chemical fume hood for 3 d and ground in a mortar. One milligram of the sample was suspended in 10 ml of LB medium containing antibiotics and incubated for a 3 h at 37°C with vigorous shaking. Then, the culture was centrifuged, washed three times with 10 ml of sterile water, resuspended in 1 ml of sterile water, spread onto an appropriate agar media, and incubated at 28–30°C for a month.

Maintenance procedures

Cultures may be maintained as 20% glycerol suspensions at −20 and −80°C. Long-term conservation is achieved by freeze-drying or in liquid nitrogen by standard procedures.

Differentiation of the genus *Actinopolymorpha* from other genera

Characteristics useful for phenotypic delineation of *Actinopolymorpha* from the other genera of the family *Nocardioidaceae* are listed in Table 222. The menaquinone systems dominated by MK-9(H_6) or MK-9(H_4), and the growth temperature range and optima are the most notable phenotypic characteristics that, along with morphological features, differentiate species of *Actinopolymorpha* from the phylogenetically neighboring genera *Flindersiella* and *Thermasporomyces*. The phosphatidylcholine-lacking polar lipid profile sharply differentiates this genus from *Kribbella*. *Actinopolymorpha* is readily distinguished by the morphological features

from the phylogenetically more distant non-mycelium-forming *Aeromicrobium*, *Marmoricola* and the majority of *Nocardioides* species. In addition, *Actinopolymorpha* can by separated by the menaquinone pattern both from the rod-shaped and mycelium-forming *Nocardioides* species and *Marmoricola*, which possess the predominant menaquinone MK-8(H_4).

Taxonomic comments

After the establishment of the genus *Actinopolymorpha* based on the study of a single strain (Wang et al., 2001), additional four species have been isolated and described on the basis of polyphasic taxonomic approach within 2008–2011. The data accumulated since 2001 show that some characteristics in the original genus description do not reflect features of all species currently composing the genus, or the detailed data provided conflict with those of individual species. The genus description therefore needs harmonization while preparing the emended description of this genus.

Differentiation of species of the genus *Actinopolymorpha*

Primary differentiation of the currently recognized species of this genus is achievable taking into consideration the colony color and morphological features, differences in salt tolerance, the composition of whole-cell sugars, fatty acids, menaquinones, and some other characteristics listed in Table 222 and outlined in the species descriptions below. When using the chemotaxonomic characteristics for differentiation purposes, the possible age- and medium-dependent shifts in the fatty acid compositions and probably in the menaquinone and whole cell sugar patterns, should be taken into account. In comparative taxonomic studies, cells must be grown and analyzed (tested) under similar conditions.

List of species of the genus *Actinopolymorpha*

1. **Actinopolymorpha singaporensis** Wang, Zhang, Xu, Ruan and Wang 2001, 472[VP]

sin.ga.po.ren′sis. N.L. fem. adj. *singaporensis* of or belonging to Singapore, signifying the country where the type strain was isolated.

Characteristics are as described for the genus and listed in Table 222. Information given below is based on the data and microphotographs provided in the original paper (Wang et al., 2001), unless indicated.

Grows usually on the agar surface; poor penetration of vegetative hyphae into the agar medium, e.g. ISP 3, may occur after prolonged cultivation. The colony color is brilliant orange on ISP 2 medium, and yellow on ISP 3, ISP 4, TSA (Difco), and Bennett's agar (Atlas, 1993). Aerial mycelium is absent or scarcely formed in old cultures on some solid media. No diffusible pigment is produced. The cells of varied size and shape (irregular rods, squarish, and coccoid) are usually observed. The cells can be arranged in small aggregates and short chains. Budding cell division and hyphal elongation by budding take place. Grows at 25–37°C; weak growth may be observable at 45°C on ISP 2 medium (Kaewkla and Franco, 2010a). Grows well in liquid TSB medium containing NaCl up to 8% and slowly with 10–15% NaCl. A lower salt resistance may be observed on other growth media (Kaewkla and Franco, 2010b, a). Utilizes maltose, dextrin, glycerol, and salicin, as sole carbon sources, but not cellobiose or lactose (Wang et al., 2008b; Wang et al., 2001). An alkaline color of the phenol red in the tests (Gordon et al., 1974) for utilization of citrate or malonate, but not succinate (Wang et al., 2008b). Hydrolyzes hypoxanthine and xanthine. Positive in the API ZYM test for esterase lipase (C8), but negative for esterase (C4) and urease (Yuan et al., 2010).

Source (type strain): soil of the primary rainforest of the Bukit Timah nature reserve, Singapore.

DNA G+C content (mol%): 69.5 (HPLC).

Type strain: IM 7744, JCM 10761, NBRC 100040, NRRL B-24113.

Sequence accession no. (16S rRNA gene): AF237815.

2. **Actinopolymorpha alba** Cao, Jiang, Wu, Xu and Jiang 2009, 2202[VP]

al′ba. L. fem. adj. *alba* white, referring to the white substrate mycelium.

Characteristics are as described for the genus and listed in Table 222. Information presented below is taken from the original paper (Cao et al., 2009), unless indicated.

Good growth occurs at 28°C on ISP 2, ISP 2, ISP 5, Czapek's agar, and potato agar, but not nutrient agar and ISP 4. The colony color is usually milk–white to gray-white on the all media tested. Sparse aerial hyphae develop on ISP 2 medium but not on the other test media. No diffusible pigments are observable, except brown melanoid pigment on tyrosine agar, ISP 7 (Kaewkla and Franco, 2010b). Branched vegetative hyphae of uneven thickness, with marked budding and swellings (Figure 266). The ranges of temperatures and salinity allowing growth are 0–7% NaCl and 10–45°C (on ISP 2) according to the original description; lower threshold values were reported (Kaewkla and Franco, 2010b, a). Utilizes dextrin, fucose, maltose, mannose, and ribose as carbon sources, but not cellobiose, lactose, glycerol, or xylitol. Negative for milk coagulation and peptonization. Hydrolyzes L-tyrosine, but not hypoxanthine, xanthine, or urea. Positive in the API ZYM tests for α-chymotrypsin, esterase (C4), β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, leucine arylamidase, α-mannosidase, naphthol-AS-BI-phosphohydrolase, but negative for acid phosphatase, alkaline phosphatase, cystine arylamidase, esterase lipase (C8), α-fucosidase, α-galactosidase, β-glucosidase, β-glucuronidase, lipase (C14), trypsin, and valine arylamidase.

Source (type strain): rhizosphere soil, Yunnan Province, China.

DNA G+C content (mol%): 66.6 (HPLC).

Type strain: YIM 48868, CCTCC AA 208030, DSM 45243, JCM 16897.

Sequence accession no. (16S rRNA gene): EF601829.

3. **Actinopolymorpha cephalotaxi** Yuan, Zhang,Yu, Sun, Wei, Liu, Li and Zhang 2010, 53[VP]

ce.pha.lo.ta′xi. N.L. gen. n. cephalotaxi of *Cephalotaxus*, of *Cephalotaxus fortunei*, a plant from which the rhizosphere soil sample was collected for isolation.

Characteristics are as described for the genus and listed in Table 222. Information presented below is taken from the original paper (Yuan et al., 2010), unless indicated.

Grows at 28°C, forming brilliant orange colonies on ISP 2, and buff or yellow on ISP 3, ISP 4, ISP 5, Czapek's agar, nutrient agar (Difco), and tomato-paste-oatmeal agar (Waksman, 1961). Aerial mycelium is absent. Buff diffusible pigment is produced on ISP 3 agar, nutrient agar and tomato-paste-oatmeal agar. Cells usually of irregular shapes, divide through apical and lateral budding, and remain attached after division, forming small aggregates and short chains (Figure 267). Grows well in the temperature range of 20–28°C, will grow at 15°C (Kaewkla and Franco, 2010b) but not at 4°C or above 37°C. Tolerates up to 5% NaCl both on ISP 2 agar (Kaewkla and Franco, 2010b) and in liquid TSB medium. Utilizes glucosamine as sole carbon sources, but not acetate, citrate, gluconate, or tartrate. Positive for milk coagulation and peptonization. H_2S is not produced. Positive in the API ZYM tests for acid and alkaline phosphatases, esterase, esterase lipase, urease, trypsin, chymotrypsin, naphthol-AS-BI-phosphohydrolase, α- and β-galactosidases, α- and β-glucosidases, *N*-acetyl-β-glucosaminidase, and α-mannosidase.

Source (type strain): rhizosphere soil of *Cephalotaxus fortunei*; Yunnan Province, China.

DNA G+C content (mol%): 69.3 (T_m).

Type strain: I06-2230, CCM 7466T, DSM 45117, KCTC 19293.

Sequence accession no. (16S rRNA gene): EU438909.

4. **Actinopolymorpha pittospori** Kaewkla and Franco 2010b, 000[VP]

pit.to.spo′ri. N.L. gen. n. *pittospori* of *Pittosporum*, isolated from *Pittosporum phylliraeoides*

Characteristics are as described for the genus and listed in Table 222. Information presented below is taken from the original paper (Kaewkla and Franco, 2010b).

Good growth on ISP 2, Bennett's agar, and half-strength potato dextrose agar (HPDA; Atlas, 1993); poor growth is observed on ISP 3, ISP 4, ISP 5, ISP 7, and nutrient agar (Atlas, 1993). Colony color is white on ISP 4, and pale yellow or yellowish white on the all other above media. Aerial mycelium is moderate to good on HPDA, scant on ISP 2 and Bennett's agar, and absent on the other test media. Diffusible pigments are not produced. Branched substrate mycelium of irregular thickness is well developed on most media. In the later stage of growth, hyphae fragment to rod-like elements or V-shaped forms. Short chains and aggregates of cells occur. Will grow between 15–27°C, but not at 4 or 37°C. Good growth is observed at a low (1%) NaCl concentration, with weak growth at 3% NaCl, as assessed on ISP 2 agar.

Source (type strain): surface-sterilized leaves of *Pittosporum phylliraeoides*; the campus of Flinders University, Adelaide, South Australia.

DNA G+C content (mol%): 69.6 (HPLC).

Type strain: PIP 143, DSM 45354, ACM 5288.

Sequence accession no. (16S rRNA gene): FJ805429.

5. **Actinopolymorpha rutila** Wang, Zhang, Xu and Li 2008b, 2445[VP]

ru.ti′la. L. fem. adj. *rutila* red inclining to golden-yellow, referring to the color of colonies.

Characteristics are as described for the genus and listed in Table 222. Information presented below is taken from the original paper (Wang et al., 2008b), unless indicated.

Colonies develop well within 3–4 d at 28°C on suitable agar media. Good growth occurs on ISP 2, ISP 5, and potato agar; moderate growth on ISP 3, ISP 4, Czapek's agar, and nutrient agar. The color of colonies is deep orange-yellow on ISP 2 and potato agar; brilliant orange-yellow on ISP 3, ISP 5, and Czapek's agar; pink orange-yellow on ISP 4 and nutrient agar. Scant aerial hyphae are formed on ISP 2 in the later stages of growth. Diffusible pigments are not produced. Branched substrate mycelia of uneven thickness are formed, and fragment in the early stages of growth. Hyphae exhibit varied degrees of fragmentation and differentiation as growth proceeds, with short to elongated rod-like or V-shaped elements typically observable in older cultures. Will grow at 15–37°C, and in the presence of 3% NaCl on ISP 2 medium; data on higher values of the above growth parameters are conflicting (Kaewkla and Franco, 2010b, a; Wang et al., 2008b). Positive oxidase reaction with 1% *p*-aminodimethylalanine oxalate. Assimilates cellobiose, lactose, maltose, mannose, melibiose, melezitose, ribose, dextrin, salicin, adonitol, glycerol, and xylitol as sole carbon sources but not arabitol or dulcitol. Acid is produced from fucose, raffinose, D-xylose, and erythritol. Utilizes malonate or succinate, but not acetate, citrate, or oxalate (tested according to Gordon et al., 1974). Negative test results for hydrolysis of DNA, Tween 60, or L-tyrosine, and for H_2S production. Hydrolyzes hypoxanthine and xanthine and decomposes urea in conventional tests (but negative for urease in the API ZYM test system; Yuan et al., 2010). Positive in the API ZYM for alkaline phosphatase, α-glucosidase, β-glucosidase, α-galactosidase, β-galactosidase, and α-mannosidase, but negative for *N*-acetyl-β-glucosaminidase, lipase (C14), β-glucuronidase, acid phosphatase, naphthol-AS-BI-phosphohydrolase, leucine arylamidase, cystine arylamidase, valine arylamidase, α-fucosidase, chymotrypsin, and trypsin. Variable results in the API ZYM for esterase (C4) and esterase lipase (C8) (Wang et al., 2008b; Yuan et al., 2010).

Source (type strain): forest soil collected in Yunnan Province, south-west China.

DNA G+C content (mol%): 67.7 (HPLC).

Type strain: YIM 45725, CCTCC AA 206004, DSM 18448, JCM 16537.

Sequence accession no. (16S rRNA gene): EF601829.

Genus III. **Aeromicrobium** Miller, Woese and Brenner 1991, 367[VP] emend. Yoon, Lee and Oh 2005c, 2174

Lyudmila I. Evtushenko and Valentina I. Krausova

A.e.ro.mi.cro′bi.um. Gr. n. *aer, aeros* air; N.L. neut. n. *microbium* microbe; N.L. neut. n. *aeromicrobium* aerobic microbe.

Small irregular rods (mostly 0.3–0.6 µm in diameter) **to coccoid forms.** Elongated rods, branched filamentous elements, and V-forms rarely occur. A marked rod-to-coccoid growth cycle can be observed. Endospores are not formed. Nonmotile or motile. Extracellular diffuse haloes or capsules can be produced. **Gram-positive** cell-wall chemotype, non-acid-fast. Colonies are non-pigmented, yellow or beige to amber-beige in color. **Chemo-organotrophs, metabolism primarily respiratory** with oxygen as the terminal electron acceptor. **Mostly catalase-positive;** negative catalase reaction may occasionally occur. Nitrate can be reduced by some species. Acids are produced oxidatively from some carbohydrates. Generally nutritionally exacting; grows aerobically on complex media based on peptone, yeast extract, and similar sources of nutrients. Some species can grow in chemically defined media. Mesophilic, optimal growth at 25–37°C; growth range is ~ 4–42°C. Mostly non-halophilic or slightly halophilic; some species are salt-requiring. Prefer a neutral to mildly alkaline pH. **The cell-wall peptidoglycan contains LL-diaminopimelic acid, along with alanine, glutamic acid, and glycine.** Menaquinones are the sole respiratory quinones detected; the tetrahydrogenated menaquinone with nine isoprene units **[MK-9(H_4)] is predominant**. **The major cellular fatty acids are octadecenoic ($C_{18:1}$ ω9*c*), hexadecanoic ($C_{16:0}$), tuberculostearic ($C_{18:0}$ 10-methyl), and 2-hydroxy hexadecanoic ($C_{16:0}$ 2-OH) acids.** Mycolates are absent. Principal polar lipids reported are diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylethanolamine, or diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol. Occur in terrestrial and aquatic environments and can be associated with plants, animals, and humans.

DNA G+C content (mol%): 65.5–75.9.

Type species: **Aeromicrobium erythreum** Miller, Woese and Brenner 1991, 367[VP].

Further descriptive information

The genus *Aeromicrobium* belongs to the family *Nocardioidaceae* and the order *Propionibacteriales* (formerly suborder *Propionibacterineae* Stackebrandt et al. 1997). The current *Aeromicrobium* species form a coherent 16S rRNA-based phylogenetic cluster which is clearly separated from other genera and species comprising the family *Nocardioidaceae* (Figure 247).

Morphology and colony appearance. The cells of *Aeromicrobium* species are typically small irregular rods (mostly 0.3–0.6 µm in width and up to 2.4 µm in length) and can be coccoid (Figure 268 and Figure 269a, b; Table 223). Longer cells can be produced by *Aeromicrobium tamlense* (up to 4.8 µm; Lee and Kim, 2007) and *Aeromicrobium halocynthiae* (up to 6.0 µm or more; Kim et al., 2010). Cells of *Aeromicrobium halocynthiae* can also form straight or curved filaments with rudimentary branching (in A1+C liquid medium containing 10 g of starch, 4 g of peptone, 2 g of yeast extract, and 1 g of calcium carbonate in 1 liter of filtered seawater; pH 7.0; Kim et al., 2010). Where reported, the cells of *Aeromicrobium* species stain Gram-positive.

[a]Based on characteristics of type strains. Symbols and abbreviations: –, negative; +, positive; v, variable between different experiments or test methods; w, weak or slow; –/w, either negative, or weak and slow; 9(H_4) and 8(H_4), menaquinone having nine and eight isoprene units, two of which are saturated; PE, phosphatidylethanolamine, PG, phosphatidylglycerol; DPG, diphosphatidylglycerol; PI, phosphatidylinositol, PL, unidentified phospholipids.

[b]Data compiled from: Miller et al. (1991), Tamura and Yokota (1994), Collins and Stackebrandt (1989b), Bruns et al. (2003), Yoon et al. (2005c), Cui et al. (2007a), Lee and Kim (2007), Kim et al. (2008b), Lee and Lee (2008), Tang et al. (2008), and Kim et al. (2010).

[c]The following characteristics were reported to be negative for all species (type strains) tested: Activities for lysine decarboxylase, ornithine decarboxylase, tryptophan deaminase; decomposition of chitin or chitinase activity (no data for *Aeromicrobium halocynthiae*); H_2S production and activities for cystine arylamidase, α-chymotrypsin, α-fucosidase, α-galactosidase, β-glucuronidase and α-mannosidase (no data for *Aeromicrobium ginsengisoli*); decomposition of xanthine (no data for *Aeromicrobium flavum*, *Aeromicrobium ginsengisoli* and *Aeromicrobium halocynthiae*).

The following characteristics were tested only for a few species (type strains) and were reported to be negative: Utilization of raffinose, dulcitol, and D-sorbitol (*Aeromicrobium ginsengisoli*, *Aeromicrobium halocynthiae*, *Aeromicrobium ponti*, and *Aeromicrobium tamlense*); utilization of tartrate (*Aeromicrobium ginsengisoli*, *Aeromicrobium ponti*, and *Aeromicrobium tamlense*); utilization of adonitol (*Aeromicrobium erythreum*, *Aeromicrobium ginsengisoli*, *Aeromicrobium halocynthiae*, and *Aeromicrobium tamlense*); utilization of benzoate (*Aeromicrobium alkaliterrae*, *Aeromicrobium ginsengisoli*, *Aeromicrobium ponti*, and *Aeromicrobium tamlense*); utilization of formate (*Aeromicrobium alkaliterrae*, *Aeromicrobium ginsengisoli*, *Aeromicrobium panaciterrae*, *Aeromicrobium ponti*, and *Aeromicrobium tamlense*); utilization of methyl-α-D-mannoside (*Aeromicrobium flavum*, *Aeromicrobium ponti*, and *Aeromicrobium tamlense*); indole production (*Aeromicrobium alkaliterrae*, *Aeromicrobium flavum*, *Aeromicrobium halocynthiae*, and *Aeromicrobium tamlense*), and xylanase activity/xylan degradation (*Aeromicrobium ginsengisoli* and *Aeromicrobium panaciterrae*).

[d]Cell size as usually observable in young cultures. Some differences in the cell size and morphology can be caused by different growth conditions; *Aeromicrobium halocynthiae* can produce filamentous elements with primary branching. In older (synchronized) cultures of some species, cells may become shorter and may consist predominantly or exclusively of shorter rods, coco-bacillary or coccoid forms (see the species descriptions for details).

[e]The lower and higher growth temperatures reported in the original species descriptions are indicated; actual growth temperature range can be slightly broader for some species (for more information, see the species description).

[f]Initial pH values of media.

[g]According to the data reported in the original species descriptions.

[h]Conflicting results obtained with the API 20NE (bioMérieux) test have been reported (Kim et al., 2008b).

[i]Basal mineral medium (Shirling and Gottlieb, 1966) without vitamins.

[j]Determined using different conventional methods, the API 20E, API 20NE, API ID32 GN (bioMérieux), and Biolog GP2 test systems, therefore the data for some species can be incomparable. See Table 224 and the original species descriptions for methods.

[k]See Lee and Lee (2008), Cui et al. (2007a), Kim et al. (2008b), and Kim et al. (2010) for methods.

Although cocci and irregular rods are characteristic of many species, little information is available on the rod–coccus growth cycle, which is characteristic of arthrobacters and many other actinobacteria. In the cycle, irregular rods in young cultures are replaced by coccoid forms in older cultures, and these coccoid forms, when transferred to fresh medium, produce outgrowths to give irregular rods again (Jones and Keddie, 2006). No correlation was observed between the age of the culture and prevalence of rod-shaped or coccoid cells for *Aeromicrobium erythreum* in TYE broth (1.6% tryptone, 1% yeast extract, 0.5% NaC1, and 0.4% D-glucose; Miller at al., 1991). The cell morphology (irregular rod-shaped cells) of *Aeromicrobium marinum* in Marine broth (MB; Difco) was also reported to remain constant irrespective of the culture age (Bruns et al., 2003). On the other hand, irregular spherical forms were reported in a 5-d-old culture of *Aeromicrobium ginsengsoli* on R2A agar (Difco; Kim et al., 2008b). Our recent observations showed that cultures of *Aeromicrobium fastidiosum* can exhibit a distinct rod–coccoid growth cycle on some organic media, e.g. on modified Corynebacterium agar (DSMZ medium No. 53) containing glucose (5 g), yeast extract (5 g), Casamino acids (10 g), NaCl (5 g), agar (15 g), and distilled water (1 liter); pH 7.0–7.2. When resting cells of old (2–3 weeks) or lyophilized cultures of this species are transferred to fresh agar medium, the cells grow as rods (mean, 0.3–0.5 × 1.8–2.2 μm) in young cultures (1–2 d) and become shorter (~3–4 fold) rods or coccoid cells in 5-d-old cultures. Most likely the irregular rods of *Aeromicrobium flavum* and elongated cells or branched filamentous elements of *Aeromicrobium halocynthiae* are also replaced by short rods and/or coccoid cells in older cultures, as can be suggested from the data and micrographs provided in the original species descriptions (Kim et al., 2010; Tang et al., 2008). The marked change of morphology during the growth cycle can probably be shown by some other *Aeromicrobium* species in synchronized cultures on suitable agar media, at least those species reportedly having both irregular rods and coccoid forms. As in arthrobacters and many other coryneform bacteria (Cure and Keddie, 1973; Jones and Keddie, 2006), the composition of the nutrient medium probably influences the extent to which the morphology of *Aeromicrobium* species changes during the growth cycle. The replacement (if any) of the (irregular) rods in cultures by coccoid or coco-bacillary forms varies with individual species and culture conditions and can take up to 5–7 d or even more.

Colonies are usually 0.5–1.5 mm in diameter; larger colonies (up to 3 mm) are occasionally formed (reported for 5 d-old culture R2A agar; Cui et al., 2007a). Colonies are typically circular, smooth, convex, and may have thin, translucent edges, probably due to production of extracellular slime as demonstrated for *Aeromicrobium marinum* (Bruns et al., 2003) and *Aeromicrobium flavum* (Tang et al., 2008). After treatments aimed at detection of proteins or acidic polysaccharides, the diffuse haloes around the *Aeromicrobium marinum* colonies stain weakly with Alcian blue, indicating that the haloes may contain acidic polysaccharides (Bruns et al., 2003). The color of colonies is white or whitish to yellow and amber beige. The colony pigment color and intensity may vary depending on growth medium and culture age, as reported, e.g. for *Aeromicrobium erythreum* (Miller et al., 1991). Diffusible brown or purple pigments can be produced under certain conditions (Miller et al., 1991).

Chemotaxonomy. All species contain LL-diaminopimelic acid (LL-A_2pm) as the diamino acid in the cell-wall peptidoglycan. The amino acid composition (LL-A_2pm, alanine, glutamic acid, and glycine) reported for *Aeromicrobium erythreum* and *Aeromicrobium fastidiosum* (Busse and Schumann, 1999; Miller et al., 1991; Tamura and Yokota, 1994) is consistent with the peptidoglycan type A3γ *sensu* Schleifer and Kandler (1972). The cell wall of the type strain of *Aeromicrobium fastidiosum* was found to have glucose, rhamnose, ribitol, and amino sugars, which are derived from at least two cell-wall anionic polymers. One of these polymers is a ribitol teichoic acid that contains an amino sugar, and another is supposedly phosphorhamnan (Tul'skaya, 2009). The major component of the respiratory quinine system is MK-9(H_4); other menaquinones, MK-8(H_4), MK-7(H_4), and MK-9(H_6), may occur in minor or trace amounts (Tamura and Yokota, 1994). A larger proportion (25.4%) of MK-8(H_4) has been reported for *Aeromicrobium flavum* (Tang et al., 2008).

The fatty acids of *Aeromicrobium* species are of complex type (Suzuki and Komagata, 1983a). The predominant components are mostly $C_{18:1}$ ω9*c* (reaching up to 68%; Tang et al., 2008), $C_{16:0}$ (up to 47%; Schumann et al., 1997), $C_{18:0}$ 10-methyl (up to 42%; Tamura and Yokota, 1994), and $C_{16:0}$ 2-OH (up to 23%; and Lee, 2008). Their proportions (and the fatty acid profiles as a whole) vary with species, and usually are influenced by the composition of media, the growth temperature, the availability of oxygen, the culture age, and analytical procedure (Lee and Lee, 2008; Lee et al., 2000; Miller et al., 1991; Park et al., 1999; Tamura and Yokota, 1994; Yoon et al., 2005c). The saturated iso- and anteiso-branched fatty acids that dominate the fatty acid profiles of many other coryneform bacteria, including members of the family *Nocardioidaceae*, occur in minor or trace amounts. Principal polar lipids reported for *Aeromicrobium erythreum* and *Aeromicrobium fastidiosum* are phosphatidylethanolamine and phosphatidylglycerol (Tamura and Yokota, 1994); in addition, Lee and Kim (2007) reported the presence of diphosphatidylglycerol in these species. A different phospholipid pattern, including phosphatidylinositol, diphosphatidylglycerol, and phosphatidylglycerol, has been reported for *Aeromicrobium tamlense* (Lee and Kim, 2007) and *Aeromicrobium ponti* (Lee and Lee, 2008); additionally three unidentified phospholipids have been indicated for *Aeromicrobium ponti* (Lee and Lee, 2008).

Analysis of polyamines in the type strains of *Aeromicrobium erythreum* and *Aeromicrobium fastidiosum* (Busse and Schumann, 1999) revealed that both strains contained a large amount of cadaverine (48.6% and 24.8%, respectively, of the polyamine content). The principal polyamine in *Aeromicrobium fastidiosum* was spermine (58.4%), whereas the second most abundant polyamine in *Aeromicrobium erythreum* was spermidine (37.2%). Putrescine and 1,3-diaminopropane occurred in minor amounts in both strains. Notably, the total polyamine concentration in *Aeromicrobium fastidiosum* was rather low.

Nutrition and growth conditions. Bacteria of this genus will grow aerobically in nutritionally complex media containing peptone and yeast extract and utilize a wide range of carbohy-

drates and other compounds as carbon sources in appropriate growth media (Table 223). The data on minimal nutritional requirements of *Aeromicrobium* species are incomplete. *Aeromicrobium fastidiosum* requires thiamine and biotin (Tamura and Yokota, 1994). *Aeromicrobium erythreum* additionally needs nicotinic acid (Miller et al., 1991). Bruns et al. (2003) reported that *Aeromicrobium marinum* will grow on a minimal, artificial seawater medium with defined carbon sources (e.g. mannitol and amino acids), a 10-vitamin solution (Balch et al., 1979) and 1 ml of trace element solution (Widdel and Bak, 1992). *Aeromicrobium panaciterrae* grows in a minimal salts medium with glucose (or some other carbon sources), vitamins, and trace elements (Cui et al., 2007a). Vitamins (biotin, thiamine, and nicotinic acid) are not necessary for growth of *Aeromicrobium alkaliterrae* (Yoon et al., 2005c). Most likely *Aeromicrobium ponti* and *Aeromicrobium tamlense* do not require vitamins for growth on basal medium ISP 9 (Shirling and Gottlieb, 1966) containing defined carbon sources (Lee and Lee, 2008; Lee and Kim, 2007).

The optimal growth temperatures (25–37°C) and the temperature ranges (4–42°C or slightly higher) vary with species (Table 223). The recognized *Aeromicrobium* species are considered to be non-salt-requiring, except for *Aeromicrobium marinum*, which is reported to be obligately salt-dependent and exhibits optimum growth at salt concentrations similar to that of sea water (Bruns et al., 2003). Some other species have also been reported to prefer salt-containing media. *Aeromicrobium halocynthiae*, which grows on A1+C agar (prepared with seawater supplemented with 0–6% NaCl), shows robust growth in the presence of NaCl in this medium, but does not grow on standard TSA medium (Difco) (Kim et al., 2010). *Aeromicrobium flavum* displays the optimal growth rate in LB broth with 1–2% NaCl (Tang et al., 2008). Bacteria of this genus prefer a neutral to mildly alkaline pH. However, they may also grow in test media with acidic (up to 4.1) or alkaline (up to 11–12.1) initial pH values (Table 223).

Genomic characteristics. The DNA G+C content of most *Aeromicrobium* species are higher than 70 mol% (up to 75.9 mol%; Kim et al., 2010); lower values (65.5 and 66.8 mol%; HPLC) have been reported for *Aeromicrobium panaciterrae* (Cui et al., 2007a) and *Aeromicrobium ginsengisoli* (Kim et al., 2008b). The current *Aeromicrobium* species form a coherent phylogenetic group based on 16S rRNA gene sequence analysis (similarity, >96%; Figure 247). The similarity based on 16S–23S ITS sequence analysis for the type strains of *Aeromicrobium erythreum* and *Aeromicrobium fastidiosum* was found to be 71.2% (Yoon et al., 1998a). The authors emphasized that the 16S–23S ITS similarity of *Aeromicrobium erythreum* was higher to the type strain of *Nocardioides jensenii* (73.1%) than to *Aeromicrobium fastidiosum*, and higher to three *Streptomyces* species (62.9–70.0%) and one *Frankia* strain (68.8%) than to some organisms of the family *Nocardioidaceae*. Likewise, *Aeromicrobium fastidiosum* had high, but slightly lower, similarity to *Nocardioides jensenii* (70.1%) and higher similarity to representatives of *Streptomyces* and *Frankia* than to most members of the family *Nocardioidaceae* used in the analysis. Similarity of the ribonuclease P RNA gene sequences between the type strains of *Aeromicrobium erythreum* and *Aeromicrobium fastidiosum*, in contrast, was highest (88% or 78.6% when nucleotide gaps were included) than between *Aeromicrobium* strains and organisms of other genera used in the study (Yoon and Park, 2000).

Bacteriophages. Four bacteriophages infectious for *Nocardioides albus*, *Nocardioides simplex*, and/or *Terrabacter tumescens* were not infectious for *Aeromicrobium erythreum* NRRL B-3381; the complete absence of plaques suggests the existence of barriers to phage adsorption or phage replication (Miller et al., 1991).

Antibiotic sensitivity and antibiotic production. The growth of the type strains of two *Aeromicrobium* species (*Aeromicrobium erythreum* and *Aeromicrobium flavum*) are inhibited by tetracycline, chloramphenicol, kanamycin, and vancomycin, as well as other antibiotics as indicated in the species descriptions (Miller et al., 1991; Tang et al., 2008). *Aeromicrobium erythreum* JCM 8359 but not *Aeromicrobium fastidiosum* JCM 8088 produces β-lactamase (Ogawara et al., 1999). The type strain of *Aeromicrobium erythreum* produces the macrolide antibiotic erythromycin A (French et al., 1970; Miller et al., 1991). The erythromycin-biosynthetic (*ery*) gene cluster of *Aeromicrobium erythreum* was cloned and characterized (Brikun et al., 2004). The 55.4-kb cluster contained 25 *ery* genes, and homologs were found for each gene in the previously characterized *ery* gene cluster from *Saccharopolyspora erythraea*. In addition, four new predicted *ery* genes were revealed (Brikun et al., 2004). The characteristics of the erythromycin resistance gene *ermA* of *Aeromicrobium erythreum* were described by Roberts et al. (1985).

Habitats and ecology. The recognized *Aeromicrobium* species have been isolated from soils of different origin, plants, air, and aquatic environments (Table 223). *Aeromicrobium halocynthiae* was recovered from the siphon tissue of a marine ascidian, *Halocynthia roretzi* (Kim et al., 2010).

The species *Aeromicrobium tamlense* and *Aeromicrobium marinum* were or could be associated with algae. *Aeromicrobium marinum* was found to occur in large numbers in the German Wadden Sea and to assimilate mannitol, which is present in seaweed in large amount as well as in algal exudates (Bruns et al., 2003; Budavari, 1989; Spencer, 1990). This bacterium, in addition, produces abundant exopolysaccharides that might serve to attach to algal surfaces (Bruns et al., 2003). The ability of another seawater species, *Aeromicrobium ponti*, to use mannitol as a carbon source and to hydrolyze cellulose (Lee and Lee, 2008) might be indicative of its association with algae as well. Recent ecological studies show that bacteria of the genus *Aeromicrobium* are distributed in various other terrestrial and aquatic environments, including low-temperature and deep subseafloor ecosystems (Glöckner et al., 2000; Hansen et al., 2007; Imazaki and Kobori, 2010; Katayama et al., 2007; Kobayashi et al., 2008; Lesaulnier et al., 2008; Rintala et al., 2008; Stevens et al., 2007; Zhang et al., 2007; Zhang et al., 2009b). Some unnamed members of this genus have been found in polluted environments, including high-level nuclear waste-contaminated sediments (Fredrickson et al., 2004), hydrocarbon-contaminated soils (Militon et al., 2010), and copper-contaminated substrates (Sun et al., 2010). They can occur on the surface of copper coins (Santo et al., 2010) and

are associated with plant tissues (Sun et al., 2010; Wang et al., 2008a) and deep-water marine sponge (Sfanos et al., 2005). Representatives of the genus also can be isolated from the skin microbiota of salamanders (Lauer et al., 2008) and humans (e.g. GenBank numbers HM336148 and HQ616221) and are also among viable microorganisms in retropharyngeal lymph nodes (organs once believed to be largely amicrobic in the absence of overt disease) of healthy wild ungulates (mule deer, *Odocoileus hemionus*; Wittekindt et al., 2010). No species or strains pathogenic for humans, other warm-blooded animals, or plants have yet been identified.

Enrichment and isolation procedures

No selective medium for the isolation of strains of *Aeromicrobium* has been described. Dilution plating and different media, e.g. R2A agar (Difco), tenfold-diluted nutrient agar (NA, Difco), and other agar media containing peptone and yeast extract may be used for isolation. Incubation is usually carried out at 25–30°C from a week to a month. Adjustment of pH to 10.0 with Na_2CO_2, as reported for *Aeromicrobium alkaliterrae* (Yoon et al., 2005c), facilitates isolation of alkalitolerant (alkaliphilic) species. Marine agar (MA, Difco) and SC-SW medium (1% soluble starch, 0.03% casein, 0.2% KNO_3, 0.2% NaCl, 0.002% $CaCO_3$, 1.8% agar, 0.005% $MgSO_4 \cdot 7H_2O$, and 0.001% $FeSO_4 \cdot 7H_2O$ in a 60:40 mixture of natural seawater and distilled water; Lee and Kim, 2007) can be used to isolate *Aeromicrobium* species from marine environments. Pre-incubation of a water sample in Marine broth (Difco) as described for isolation of *Aeromicrobium marinum* (Bruns et al., 2003) can be useful. When isolating strains of *Aeromicrobium* species, selective (semi-selective) media may be developed on the basis of characteristics listed in Table 223, the minimal nutritional requirements of *Aeromicrobium* species, and resistance to certain antibiotics. Characteristics of environmental samples should be taken into account. Alkaline pre-treatment before serial dilution and plating, suggested for isolation of some bacteria (Påhlson et al., 1986; Wakisaka et al., 1982), facilitates reducing numerous Gram-negative bacteria. The filtration of (suspended) environmental samples through membrane filters with a pore size of 0.45 or 0.65 µm or other approaches may be useful to separate small cells of *Aeromicrobium* (which may be even smaller in environmental samples) from large-sized microorganisms occurring in the same sample.

Maintenance procedures

Cultures may be maintained as 20% glycerol suspensions at −20 and −70°C. Long-term conservation is achieved by freeze-drying by standard procedures.

Differentiation of the genus *Aeromicrobium* from other genera

Table 214 lists the phenotypic characteristics differentiating *Aeromicrobium* from other genera of the family *Nocardioidaceae*. *Aeromicrobium* can be easily distinguished from the genera and species comprising mycelium-forming organisms on the basis of cell morphology. The predominant menaquinone MK-9(H_4) is the most salient characteristic which differentiates *Aeromicrobium* from all members of the genera *Nocardioides* and *Marmoricola*. Other chemotaxonomic characteristics which may serve to distinguish *Aeromicrobium* from related genera with LL-A_2pm in the cell wall include the profiles of cellular fatty acids, polar lipids, polyamines, and probably the composition of cell-wall polysaccharides.

Taxonomic comments

The genus *Aeromicrobium* with the type species *Aeromicrobium erythreum* was described by Miller et al. (1991) to accommodate the strain "*Arthrobacter*" sp. NRRL B-3381, an unusual non-mycelium-forming producer of the macrolide antibiotic erythromycin A, that differed in many ways from *Arthrobacter sensu stricto*. The second species, *Aeromicrobium fastidiosum*, was added to the genus by Tamura and Yokota (1994) as a result of the reclassification of *Nocardioides fastidiosa* (Collins and Stackebrandt, 1989a, 1989b).

Eight remaining *Aeromicrobium* species included in this volume were described within the 2003–2010 period on the basis of taxonomic study of single environmental isolates. The descriptions relied on 16S rRNA gene sequence analysis, DNA-DNA hybridization studies (examined in cases of high 16S rRNA sequence similarity), and phenotypic traits. The DNA-DNA similarities between *Aeromicrobium* species obtained by different methods ranged from very low (3–11.5%; Cui et al., 2007a; Tang et al., 2008; Yoon et al., 2005c) to high (up to 63.5% for the *Aeromicrobium halocynthiae-Aeromicrobium ponti* pair; Kim et al., 2010). The original genus description (Miller et al., 1991), which was based on one strain and included many features specific for this strain, was emended by Yoon et al. (2005c) to take into account other relevant data accumulated by 2005.

Differentiation of species of the genus *Aeromicrobium*

Phenotypic characteristics useful in distinguishing the currently recognized ten species of the genus *Aeromicrobium* are listed in Table 224. Additional characteristics useful for differentiation are given in Table 223 and in the species descriptions below. Since many test results can be influenced by the test method, a comparative experimental study of phenotypic characteristics of a novel isolate and type strains of recognized species rather than comparisons with data presented is recommended (Schumann et al., 2009; Tindall et al., 2010).

[a]Based on characteristics of type strains. Symbols: −, negative; +, positive; v, variable between experiments; w, weakly positive.

[b]See Table 223 for references.

[c]Color intensity and shade may vary depending on growth conditions; for details concerning *Aeromicrobium erythreum*, see the species description.

[d]Identical test results (unless indicated) were obtained by using both conventional methods and the API test systems (data for *Aeromicrobium erythreum*, *Aeromicrobium alkaliterrae*, *Aeromicrobium fastidiosum*, *Aeromicrobium marinum*, and *Aeromicrobium panaciterrae*). The results for *Aeromicrobium ponti* and *Aeromicrobium tamlense* were obtained using ISP 9 (Shirling and Gottlieb, 1966) as the basal medium (Lee and Lee, 2008; Lee and Kim, 2007). API test systems (bioMérieux) were used to obtain the data for *Aeromicrobium ginsengisoli* (Kim et al., 2008b) and *Aeromicrobium halocynthiae* (Kim et al., 2010), and the Biolog GP2 test system was used to obtain the data for *Aeromicrobium flavum* (Tang et al., 2008).

[e]The opposite result was obtained using the API test system (Kim et al., 2008b).

List of species of the genus *Aeromicrobium*

1. **Aeromicrobium erythreum** Miller, Woese and Brenner 1991, 367[VP]

e.ryth′re.um. N.L. neut. adj. *erythreum* intended to mean erythromycin-producing.

Characteristics are as described for the genus and listed in Table 223. Additional information given below is taken from the original paper (Miller et al., 1991) unless indicated. Predominantly irregular rods to coccoid forms (0.5 × 0.5–1.2 µm; Figure 268) in TEY broth (1.6% tryptone, 1% yeast extract, 0.5% NaC1, and 0.4% D-glucose) at all growth phases (24, 48, and 120 h). Cells are non-motile. Colonies are beige to amber beige and 1 mm in diameter after 3 d of cultivation on TYE agar medium (1% tryptone, 0.5% yeast extract, 0.8% NaCl, and 1.5% agar) at 32°C. Colonies sometimes have thin, translucent edges. The colony color changes to a shade of yellow on media allowing even slight acid production and to distinct yellow (e.g. on R2YE medium containing sucrose; Hopwood et al., 1985) or other media (Miller et al., 1991; Tamura and Yokota, 1994). Diffusible brown or purple pigments may be produced on R2YE plates (but are not observed on TYE agar) after extended incubation at 32°C. The optimum growth temperature is 35 ± 2°C; no growth occurs at 18°C or 43°C. Grows in nutritionally complex media. Biotin, nicotinic acid, and thiamine are required for growth in chemically defined media. A wide range of organic compounds are utilized as sole or principal carbon plus energy sources for growth (Table 223). Acid production from carbohydrates is generally very weak, as determined using the phenol red indicator medium (Difco), but growth on fructose gives readily detectable acidification. The type strain produces the macrolide antibiotic erythromycin A (which can be detected by standard growth inhibition assays with susceptible bacteria on various media). The strain tested using a Gram-positive minimal inhibitory concentration (MIC) panel (Baxter, Sacramento, CA) is sensitive to amikacin,

cefotaxime, ceftriaxone, chloramphenicol, ciprofloxacin, gentamycin, hygromycin, kanamycin, neomycin, oxacillin, streptomycin, sulfamethoxazole, tetracycline, thiostrepton, vancomycin, and viomycin. Resistant to amoxicillin, ampicillin, cefamandole, clindamycin, erythromycin, imipenem, naladixic acid, nitrofurantoin, norfloxacin, penicillin, rifampin, spiramycin, and tylosin. Ogawara et al. (1999) reported that benzylpenicillin potassium inhibited growth at a concentration of 50 μg/ml, but not at 10 μg/ml.

The major compounds of polyamine pattern include cadaverine (48.6%) and spermidine (37.2%); other compounds, i.e. spermine, 1,3-diaminopropane, and putrescine, occur in minor amounts (Busse and Schumann, 1999). The predominant menaquinone is MK-9(H_4), with minor amounts of MK-7(H_4) and MK-8(H_4) (Tamura and Yokota, 1994). The major phospholipids are phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol (Lee and Kim, 2007; Tamura and Yokota, 1994). The major (>5%) fatty acids, as determined in cells grown under various conditions and harvested at different growth phase were reported to be $C_{18:0}$ 10-methyl (16.2–39%), $C_{18:1}$ ω9*c* (15.1–29.1%), $C_{16:0}$ (16.2–25.2%), $C_{16:0}$ 2-OH (11.3–14.4%), $C_{17:0}$ 10-methyl (0.3–9.5%), and $C_{18:0}$ (4.3–10.9%) (Lee and Lee, 2008; Lee et al., 2000; Miller et al., 1991; Park et al., 1999; Tamura and Yokota, 1994). A higher content of $C_{16:0}$ (47%) and lower proportions of other acids were detected for cells harvested from trypticase soy broth (Difco) after incubation at 28°C for 24–48 h (Schumann et al., 1997).

Source (type strain): tropical soil in Puerto Rico.

DNA G+C content (mol%): 71–73 (T_m).

Type strain: NRRL B-3381, ATCC 51598, DSM 8599, JCM 8359, LMG 16472, NBRC 15406, NRRL B-3381.

Sequence accession no. (16S rRNA gene): AF005021

2. **Aeromicrobium alkaliterrae** Yoon, Lee and Oh 2005c, 2174[VP]

al.ka.li.ter′ra.e. N.L. n. *alkali* (from Arabic *al-qalyi*, the ashes of saltwort), soda ash; L. gen. n. *terrae* of the soil or earth; N.L. gen. n. *alkaliterrae* of alkaline soil.

Characteristics are as described for the genus and listed in Table 223. Additional information given below is taken from the original paper (Yoon et al., 2005c) unless indicated. Small rods (0.3–0.5 × 0.8–1.4 μm) or cocci. No motility by flagella. Colonies are yellow and 1.0–1.5 mm in diameter after 7 d of cultivation at 25°C on nutrient agar (Difco). Capable of growth on simple chemically defined media, including ISP 9 medium (Shirling and Gottlieb, 1966) supplemented with glucose or other carbon sources. No growth occurs under anaerobic conditions on trypticase soy agar (TSA; Difco) or on TSA supplemented with nitrate. Grows at 35°C, but not at 37°C. Tolerates NaCl up to 8% in trypticase soy broth (TSB; Difco), but optimal growth is observed when no salt is added. Growth occurs at pH 6.0 and pH 11.0, but not at pH 5.5 or 11.5 (initial pH values of medium, TSB). Displays the ability to hydrolyze Tweens 20, 40, and 60. The major fatty acids (5% or more), as determined in cultures grown on TSA and MA at 25°C for 6 d, are $C_{16:0}$ (34.1 and 33.8%), $C_{18:0}$ 10-methyl (16.3 and 20.9%), $C_{16:0}$ 2-OH (17.6 and 15.5%), $C_{18:1}$ ω9*c* (5.7 and 9.9%), and $C_{17:0}$ 10-methyl (5.0 and 1.0%), respectively. Generally similar proportions of the above acids, except for slightly decreased $C_{18:1}$ ω9*c* (2.3%) were reported by Lee and Lee (2008) for cells grown on TSA agar at 30°C for 5 d.

Source (type strain): an alkaline soil in Kwangchun, Korea.

DNA G+C content (mol%): 71.5 (HPLC).

Type strain: strain KSL-107, KCTC 19073, DSM 16824, JCM 13518.

Sequence accession no. (16S rRNA gene): AY822044.

3. **Aeromicrobium fastidiosum** (Collins and Stackebrandt 1989b) Tamura and Yokota 1994, 610[VP] (*Nocardioides fastidiosa* Collins and Stackebrandt 1989b, 293)

fas.ti.di.o′sum. L. neut. adj. *fastidiosum* fastidious, referring to the nutritionally fastidious nature of the organism when it is first isolated.

Characteristics are as described for the genus and listed in Table 223. Additional information given below is taken from the original descriptions (Collins and Stackebrandt, 1989b; Tamura and Yokota, 1994), unless indicated. Irregular rods (average, 0.4–0.5 × 1.5–2.2 μm) in young culture (1–2 d) on modified CB agar at 26°C (recent observation). The rods fragment and become shorter as growth proceeds (usually after 3 d) and can be short cell chains at this stage. After 5–6 d of culture, coco-bacillary to coccoid cells, usually single or in pairs (recent observation), predominate. In contrast to all other *Aeromicrobium* species, *Aeromicrobium fastidiosum* is motile. Colonies are white or grayish-white. Grows in nutritionally complex media. Biotin and thiamine are required for growth in a suitable minimal salts medium with glucose. Growth occurs at 30°C, but not at 40°C. A wide range of organic compounds are utilized as sole or principal carbon plus energy sources for growth (Table 223), including L-phenylalanine, L-threonine, tyrosine, butanol, crotonate, dodecane, hexadecane, oxalacetate, and pentoate. Acid is produced from glucose. The cell-wall polysaccharides contain glucose, rhamnose, an aminosugar, and ribitol, which originate from at least two anionic polymers, i.e. the ribitol-based teichoic acid and supposedly phosphorhamnan (Tul'skaya, 2009). *Aeromicrobium fastidiosum* is characterized by a rather low concentration of polyamines; the polyamime pattern includes spermine (58.4%), cadaverine (24.8%), and minor amounts of putrescine, spermidine, and 1,3-diaminopropane (Busse and Schumann, 1999). The major menaquinone is MK-9(H_4), with minor amounts of MK-9(H_6) and MK-8(H_4). Principal phospholipids are phosphatidylethanolamine, phosphatidylglycerol, and diphosphatidylglycerol (Lee and Kim, 2007; Tamura and Yokota, 1994). The major fatty acids (>5%) determined in cells grown under different conditions are $C_{18:1}$ ω9*c* (12.3–48.2%), $C_{18:0}$ 10-methyl (9.1–42%), $C_{16:0}$ 2-OH (8.9–23.2%), $C_{16:0}$ (10–18.3%), $C_{18:0}$ (6.1–16.1%), and $C_{17:0}$ 10-methyl (<1–8.7%) as reported by Lee and Lee (2008), Lee et al. (2000), Park et al. (1999), and Tamura and Yokota (1994).

Source (type strain): herbage.

DNA G+C content (mol%): 71–72 (T_m).

Type strain: strain J41, ATCC 49363, DSM 10552, IFO (now NBRC) 14897, JCM 8088, LMG 16205, NCIB (now NCIMB) 12713, VKM Ac-1324.

Sequence accession no. (16S rRNA gene): AF005022; X53189, X76862, Z78209.

4. **Aeromicrobium flavum** Tang, Zhou, Zhang, Mao, Luo, Wang and Fang 2008, 1862[VP]

fla′vum. L. neut. adj. *flavum* yellow, referring to the colony color.

Characteristics are as described for the genus and listed in Table 223. Additional information given below is taken from the original description (Tang et al., 2008). Cells are mostly irregular rods (ca. 0.2–0.4 in width and up to 1.2 μm in length) as observed after 16 h of culture on LB agar, and become shorter in a 2-d-old culture. The cells are surrounded by an amorphous polysaccharide-like layer and form conglomerates. No motility by flagella. Colonies are yellow pigmented. Grows readily in nutritionally complex media at 25–37°C but not at 10 and 42°C. The optimum NaCl concentration for growth is 1–2% (tested in LB broth). In addition to characteristics listed in Table 223, the type strain shows positive test reactions in the Biolog GP2 test system for D-psicose, turanose, α-ketovaleric acid, γ-hydroxybutyric acid, and D-fructose-6-phosphate. Negative responses have been recorded for D-arabitol, L-fucose, α-cyclodextrin, glycogen, mannan, *N*-acetyl-β-D-mannosamine, amygdalin, L-alanyl glycine, arbutin, L-asparagine, 2′-deoxyadenosine, putrescine, sedoheptulosan, glycyl-L-glutamic, α-hydroxybutyric, and L-lactic acids. Displays also negative responses in the Biolog GP2 plate for assimilation of dextrin, thymidine, and uridine, which along with other features listed in Table 223 and Table 224 differentiate this species from its phylogenetically closest relative *Aeromicrobium tamlense* (98.4% 16S rRNA gene sequence similarity). The DNA-DNA relatedness value between the type strains of these two species was reported to be 35%. Susceptible to tetracycline, chloramphenicol, kanamycin, vancomycin, erythromycin, rifampicin, and tobramycin; resistant to penicillin and nalidixic acid (determined by the agar-diffusion method using antibiotic-impregnated discs as described by Buczolits et al., 2002). The major menaquinones are MK-9(H_4) (74.6%) and MK-8(H_4) (25.4%). The fatty acids (1% or more) recorded for cells grown for 24 h at 30°C in trypticase soy broth (Difco) include $C_{18:1}$ ω9*c* (68.4%), $C_{18:0}$ (11.7%), $C_{16:0}$ (8.7%), $C_{16:0}$ 2-OH (5.3%), $C_{18:0}$ 10-methyl (2.3%), and $C_{16:1}$ ω6*c* (1.0%).

Source (type strain): air (on the campus of Wuhan University, China).

DNA G+C content (mol%): 73.3 (T_m).

Type strain: TYLN1, CCTCC AB 206046, DSM 19355.

Sequence accession no. (16S rRNA gene): EF133690.

5. **Aeromicrobium ginsengisoli** Kim, Park, Im and Yang 2008b, 2028[VP]

gin.sen.gi.so′li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of/from ginseng soil.

Characteristics are as described for the genus and listed in Table 223. Additional information given below is taken from the original description (Kim et al., 2008b). Cells (typically 0.3–0.4 × 0.5–1.2 μm) display coccoid forms after 5 d in culture at 30°C on R2A agar (Difco). No motility was observed with a light microscope. Colonies are white on R2A after 5 d. Will grow in nutritionally complex media at temperatures up to 30°C or slightly higher, but not at 37°C. Grows on R2A agar with 3% NaCl and weakly with 4% NaCl. No growth on MacConkey agar. In contrast to all other recognized *Aeromicrobium* species, this species was reported to display negative catalase reaction. Oxidase activity (evaluated by using 1% *p*-aminodimethylaniline oxalate) is positive. Reduces nitrate to nitrite, but not to nitrogen gas. Positive for assimilation of D-fucose, D-lyxose, ethanol, fumarate, L-asparagine, glutamate, glutamine, L-leucine, L-phenylalanine, L-proline, L-serine, L-tryptophan, and L-tyrosine in the API 20E and API 20NE tests (bioMérieux). Negative for assimilation of L-fucose, melibiose, L-xylose, *myo*-inositol, methanol, glycogen, 3- and 4-hydroxybenzoate, glutarate, 2- and 5-ketogluconate, itaconate, maleic acid, oxalate, L-arginine, L-aspartate, L-cysteine, L-glycine, L-histidine, L-isoleucine, L-lysine, L-methionine, L-threonine, and L-valine. Fatty acids determined in cells grown on trypticase soy agar (Difco) at 30°C for 48 h include $C_{16:0}$ (32.7%), $C_{18:0}$ 10-methyl (20.6%), $C_{18:0}$ (12.9%), $C_{17:0}$ (3.2%), $C_{19:0}$ 10-methyl (3.1%), and $C_{17:0}$ 10-methyl (2.4%).

Source (type strain): soil of a ginseng field in Daejeon, South Korea.

DNA G+C content (mol%): 66.8 (HPLC).

Type strain: Gsoil 098, GBS 39, JCM 14732, KCTC 19207.

Sequence accession no. (16S rRNA gene): AB245394.

6. **Aeromicrobium halocynthiae** Kim, Yang, Sohn and Kwon 2010, 2797[VP]

ha.lo.cyn.thi′a.e. N.L. gen. n. *halocynthiae* of *Halocynthia roretzi*, the ascidian from which the type strain was isolated.

Characteristics are as described for the genus and listed in Table 223. Additional information presented below is taken from the original paper (Kim et al., 2010). Cells are typically elongated rods (approximately 0.4–0.5 × 4.1–6.0 μm); straight, curved and rudimentarily branched filaments can be produced (e.g. in culture growing in A1+C liquid medium at 25°C). Colonies are light yellowish and 0.6–1 mm in diameter after incubation on A1+C agar plates at 25°C for 5 d. Grows on marine agar (Difco) and some other complex media but not on standard TSA medium (Difco). Will grow on A1+C agar with 0–6% NaCl, but NaCl is required for robust growth. Grows at 10–42°C (but not at 7 and 45°C), with optimal growth at 25°C. Will grow in liquid A1+C medium over a pH range of 5.0–10.0. The following carbon sources are utilized (API 50 CHE system): turanose, D-tagatose and 5-ketogluconate. Erythritol, D-arabinose, L-xylose, adonitol, methyl-β-xyloside, dulcitol, sorbitol, methyl α-D-mannoside, methyl-α-D-glucoside, *N*-acetylglucosamine, amygdalin, arbutin, esculin, salicin, melezitose, raffinose, starch, glycogen, xylitol, β-gentiobiose, D-lyxose, D-fucose, L-fucose, D-arabitol, L-arabitol, and 2-ketogluconate are not utilized as sole carbon and energy sources. Oxidizes arabinose, does not oxidize glucose, mannitol, inositol, sorbitol, rhamnose, sucrose, melibiose or amygdalin. α-Galactosidase and β-glucuronidase activities are not detected. The type strain produces taurocholic acid, a bile acid, as a major secondary metabolite. Predominant fatty acids (>5%) are $C_{18:1}$ ω9*c* (35.2%), $C_{16:0}$ (31.5%), $C_{18:0}$ 10-methyl (21.1%), and $C_{18:0}$ (5.5%). The hydroxylated fatty acid ($C_{16:0}$ 2-OH), which typically occurs in significant amounts in all other recognized *Aeromicrobium* species, has been not detected in *Aeromicrobium halocynthiae*. This species

is phylogenetically closest to *Aeromicrobium ginsengisoli*, *Aeromicrobium erythreum* and *Aeromicrobium ponti* (97.7, 97.6, and 97.5% 16S rRNA gene sequence similarities, respectively). The DNA–DNA similarity values between the type strain of *Aeromicrobium halocynthiae* and the type strains of the aforementioned species are 49.6–63.5%.

Source (type strain): siphon tissue of a marine ascidian, *Halocynthia roretzi*, collected at a depth of 15 m near Kyung-Po beach, coast of Gangneung, Korea.

DNA G+C content (mol%): 75.9 (HPLC).

Type strain: KME 001, JCM 15749, KCCM 90079.

Sequence accession no. (16S rRNA gene): FJ042789.

7. **Aeromicrobium marinum** Bruns, Philipp, Cypionka and Brinkhoff 2003, 1922[VP]

ma.ri′num. L. neut. adj. *marinum* of the sea, marine.

Characteristics are as described for the genus and listed in Table 223. Additional information presented below is taken from the original description (Bruns et al., 2003) unless indicated. Cells are irregular rods (0.3–0.5 × 0.7–1.3 μm; Figure 269a,b). The morphology is reported to remain constant in Marine broth (Difco), irrespective of the culture age (up to 10 d). No flagella, pili, or other appendages are observed. Colonies are ivory-colored and 0.5–1.0 mm in diameter; diffuse haloes of different size (Figure 269c) are observed around the colonies. It is the sole species within the genus proven to be salt-requiring so far. Grows well in ASW/YPG medium (1 liter of artificial sea water, 0.3% yeast extract, 0.6% peptone, and 0.3% glucose) with salt concentrations in the range 0.63–10.7%. A maximal growth rate is observable at 5.35%; growth is weak at 0.08% salinity and absent when no salts are added. The type strain grows with carbon sources such as crotonic acid, fumarate, 2-oxoglutarate, arginine, and glutamic acid but not with pimelic acid, nicotinic acid, salicylic acid, ethanol, propanol, butanol, asparagine, aspartic acid, cysteine, glutamine, glycine, or histidine. Cannot grow with D-glucose as a carbon source in minimal salts media containing vitamins and microelements (Bruns et al., 2003; Cui et al., 2007a). Unable to hydrolyze vegetable oil. Bruns et al. (2003) and Lee and Lee (2008) reported the following major fatty acids (>5%) for the type strain: $C_{18:1}$ ω9*c* (28.5 and 21.7%), $C_{16:0}$ (15.0 and 16.6%), $C_{16:0}$ 2-OH (14.0 and 7.9%), and $C_{18:0}$ 10-methyl (12.5 and 8.2%). Lee and Lee (2008) reported additionally significant amounts of $C_{17:0}$ (9.9%) and $C_{18:0}$ (11.5%) for cells harvested from TSA agar (Difco) after incubation at 30°C for 5 d.

Source (type strain): surface waters of the German Wadden Sea.

DNA G+C content (mol%): 70.6 (HPLC).

Type strain: T2, DSM 15272, JCM 13314, LMG 21768.

Sequence accession no. (16S rRNA gene): AY166703.

8. **Aeromicrobium panaciterrae** Cui, Im, Yin, Lee, Lee and Lee 2007a, 690[VP]

pa.na.ci.ter′ra.e. N.L. n. *Panax, -acis* scientific name of ginseng; L. n. *terra* soil; N.L. gen. n. *panaciterrae* of soil of a ginseng field.

Characteristics are as described for the genus and listed in Table 223. Information presented below is taken from the original paper (Cui et al., 2007a). Cells are short rods (0.2–0.4 × 1.0–1.5 μm) after culture for 3 d in modified R2A broth. No motility was observed with a light microscope. Colonies grown on R2A agar (Difco) for 5 d are light yellowish white and reach 1–3 mm in diameter. Grows well at 15–30°C (but not at 4 or 35°C), in the pH range of 5.0–8.5, and in the presence of up to 3% NaCl on R2A agar. Will grow readily on nutrient agar (0.5% peptone, 0.3% beef extract, and 1.5% agar). Growth on TSA agar is slow and looks like very thin layer on the agar surface after 5 d at 30°C. No growth on MacConkey agar. Capable of growth in suitable minimal salts media with glucose, vitamins, and trace elements. Utilizes melibiose, L-lactate, D-glycogen, and glycine as carbon sources but not D-fucose, D-lyxose, L-lysine, and DL-serine. Does not produce acid or gas from glucose oxidatively or fermentatively as determined using O-F basal medium (Atlas, 1993) with bromothymol blue. The major components (>5%) of the fatty acid profile determined in cells grown in modified R2A broth for 6 d are $C_{18:0}$ 10-methyl (14.5%), $C_{16:0}$ (13.0%), $C_{16:0}$ 2-OH (12.8%), $C_{17:0}$ 10-methyl (11.9%), $C_{16:0}$ 10-methyl (11.7%), $C_{16:1}$ ω7*c*, $C_{15:0}$ iso 2-OH (6.6%), and $C_{18:1}$ ω9*c* (5.3%).

Source (type strain): soil of a ginseng field in Pocheon Province, South Korea.

DNA G+C content (mol%): 65.5 (HPLC).

Type strain: Gsoil 161, KCTC 19131, DSM 17939, CCUG 52476.

Sequence accession no. (16S rRNA gene): AB245387.

9. **Aeromicrobium ponti** Lee and Lee 2008, 990[VP]

pon′ti. L. gen. n. *ponti* of the sea, belonging to the sea, referring to the isolation of the type strain from seawater.

Characteristics are as described for the genus and listed in Table 223. Information presented below is taken from the original paper (Lee and Lee, 2008). Cells are irregular rods (0.7 × 2.4 μm) as observed in 24-h culture on TSB at 30°C. Colonies are yellow in color and reach 0.8–1.2 mm in diameter after 5 d on TSA (Difco). Neither motility nor flagella are observed. Will grow on simple chemically defined media, e.g. ISP 9 (Shirling and Gottlieb, 1966) with glucose or other carbohydrates, sugar alcohols, or organic acids (Table 223). Does not grow on ISP 9 medium with D-arabinose, melezitose, methyl-α-D-glucoside, or *meso*-erythritol. Grows well at 30–37°C; can grow at 42°C or even higher. Displays growth in the pH range of 4.1–12.1 (initial pH of medium, TSA), but the optimal pH for growth is 5.1–7.1. Tolerates 10% NaCl as tested on ISP 2 agar medium. Able to hydrolyze carboxymethylcellulose. The polar lipids are phosphatidylinositol, diphosphatidylglycerol, phosphatidylglycerol, and three unidentified phospholipids. Predominant fatty acids determined in cells grown on TSA agar at 30°C for 5 d are $C_{18:1}$ ω9*c* (34.7%), $C_{16:0}$ (19.7%), $C_{16:0}$ 2-OH (14.8%), and $C_{18:0}$ 10-methyl (11.0%).

Source (type strain): seawater from the coast of Jeju Island, Republic of Korea.

DNA G+C content (mol%): 74.0 (HPLC).

Type strain: HSW-1, DSM 19178, KACC 20565.

Sequence accession no. (16S rRNA gene): AM778683.

10. **Aeromicrobium tamlense** Lee and Kim 2007, 339[VP]

tam.len′se. N.L. neut. adj. *tamlense* of or belonging to Tamla, the old name of Jeju, Republic of Korea, the site of isolation of the type strain.

Characteristics are as described for the genus and listed in Table 223. Additional information presented below is taken from the original paper (Lee and Kim, 2007) unless indicated. Cells are irregular rods ranging in size from 0.4–0.6 × 0.8–1.2 µm to 0.5 × 3.8–4.8 µm, as observed in 3-d-old cultures on YE-SW agar at 30°C. Colonies are yellow and 0.6–0.8 mm in diameter after incubation for 5 d on YE-SW at 30°C. No growth occurs at 4 or 45°C. Growth is observed at pH 10.1 (initial pH of medium, TSA) and in the presence of up to 5% NaCl (tested on ISP 2 medium; Shirling and Gottlieb, 1966). Grows in simple chemically defined media, e.g. ISP 9 (Shirling and Gottlieb, 1966), with glucose or other carbohydrates, sugar alcohols, or organic acids (Table 223) and also with L-ribose, or methyl-α-glucoside. The following carbon sources are not utilized as sole carbon and energy sources: D-arabinose, D-melezitose, 2,3-butanediol, *meso*-erythritol, and 1,2-propanediol. The type strain displays positive responses in the Biolog GP2 plate for assimilation of dextrin, thymidine, and uridine (Tang et al., 2008), which, along with other characteristics listed in Table 223 and Table 224, may serve to differentiate *Aeromicrobium tamlense* from the phylogenetically closest species *Aeromicrobium flavum.* Principal phospholipids include phosphatidylinositol, diphosphatidylglycerol, and phosphatidylglycerol. The major fatty acids in cells harvested from TSA agar (Difco) after incubation at 30°C for 5 d are $C_{18:1}$ ω9*c* (47.2%), $C_{16:0}$ (13.8%), $C_{18:0}$ (13.6), $C_{18:0}$ 10-methyl (8.7%), and $C_{16:0}$ 2-OH (6.8%).

Source (type strain): dried seaweed collected from Samyang beach in Jeju Island, Korea.

DNA G+C content (mol%): 72.7 (HPLC).

Type strain: SSW1-57, JCM 13811, CIP 09549, DSM 19087, NRRL B-24466.

Sequence accession no. (16S rRNA gene): DQ411541.

Genus IV. **Kribbella** Park, Yoon, Shin, Suzuki, Kudo, Seino, Kim, Lee and Lee 1999, 750^VP emend. Sohn, Hong, Bae and Chun 2003, 1007

Lyudmila I. Evtushenko and Valentina I. Krausova

Krib.bel′la. N.L. fem. dim. n. *Kribbella* arbitrary name formed from the acronym of the Korea Research Institute of Bioscience and Biotechnology, KRIBB, where taxonomic studies of this taxon were performed.

Extensively branched vegetative (substrate) hyphae, mostly ~0.4–0.7 µm in diameter, growing on the surface of, and penetrating, agar media. **Aerial hyphae are typically produced** on suitable agar media. Both the substrate and aerial **hyphae usually undergo various degrees of fragmentation** eventually **resulting in irregular rod-shaped to coccoid, nonmotile, elements**. Short chains of well-to-poorly differentiated conidia may occur on aerial hyphae. Bud-like cells, apical swellings, and cell conglomerates may be produced by the substrate mycelium. No endospores are formed. **Colonies are pasty to soft-leathery**, often with lichenous shape and usually no distinct coloration. Diffusible pigments are usually not produced, except for melanoid pigments characteristic of some species. **Gram-stain-positive**, but may be variable. Non-acid-fast. **Chemoorganotrophs, having a respiratory type of metabolism**, with a potential for mixotrophy and metabolic flexibility. **Grow well under aerobic conditions** on standard laboratory media, including the chemically defined (synthetic) media. Some species show also weak growth under anaerobic conditions. Catalase-positive. Oxidase test reaction intensity varies with species. Utilize a wide range of carbon and nitrogen sources and possess a significant spectrum of hydrolytic activities. Mesophilic, optimal growth temperature is ~28–30°C; the lower and higher growth temperatures reported for different species are 8°C and 45°C. Usually non-halophilic and prefer a neutral to mildly alkaline pH; some species grow at initial pH values of 10 and slightly below 5.0. **The cell-wall peptidoglycan contains LL-diaminopimelic acid**, along with alanine, glutamic acid, and glycine. The muramic acid residue of the peptidoglycan is ***N*-acetylated.** The **main secondary cell-wall polymer is teichuronic or teichulosonic acid.** Menaquinones are the sole respiratory quinones detected; the tetrahydrogenated menaquinone with nine isoprene units **[MK-9(H_4)] is the major component**. **The saturated iso- and anteiso branched acids ($C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso) are the main** cellular fatty acids, with **$C_{15:0}$ anteiso usually contributing a maximal proportion**. Monounsaturated iso-branched, saturated 9-methyl branched fatty acids typically occur and may constitute significant amounts. Other fatty acids, including 2-hydroxy and 10-methyl branched acids may occur in minor or trace quantities. Mycolates are absent. **The diagnostic component of the polar lipid patterns is phosphatidylcholine** (PC); additional principal polar lipids reported are diphosphatidylglycerol (DPG), phosphatidylglycerol (PG), and phosphatidylinositol (PI).

Natural habitats are various terrestrial environments; some organisms are associated with plants and fungi, and occur in the human skin microbiome.

DNA G+C content (mol%): 67–71.3 (T_m; HPLC).

Type species: **Kribbella flavida** Park, Yoon, Shin, Suzuki, Kudo, Seino, Kim, Lee and Lee 1999, 750^VP.*

Further descriptive information

The genus *Kribbella* belongs to the family *Nocardioidaceae*, order *Propionibacteriales.* Based on the 16S rRNA gene sequence analysis, the current 16 *Kribbella* species form a tight, clearly separated phylogenetic cluster (Figure 247) with a high 16S rRNA gene sequence similarity (>97.5% and up to 99.6%).

Morphology and colony appearance. Aerial mycelium varies in abundance, depending on growth media and the individual strain or species, and at times is discernible only microscopically or lacking, e.g. on some agar media rich in organics.

of distilled water; pH 6.7±0.5.

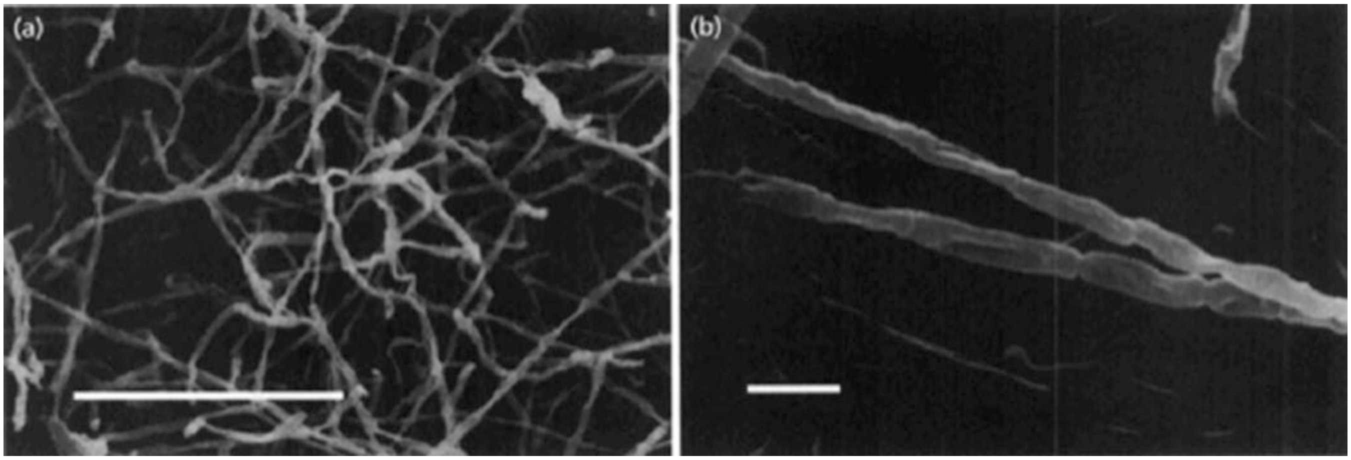

FIGURE 270. Aerial mycelium of *Kribbella flavida* on oatmeal agar (ISP 3 medium). Scanning electron micrographs. Bars = 10 µm (a) and 1 µm (b). (Reproduced with permission from Park et al., 1999. Int. J. Syst. Bacteriol. *49*: 743–752.)

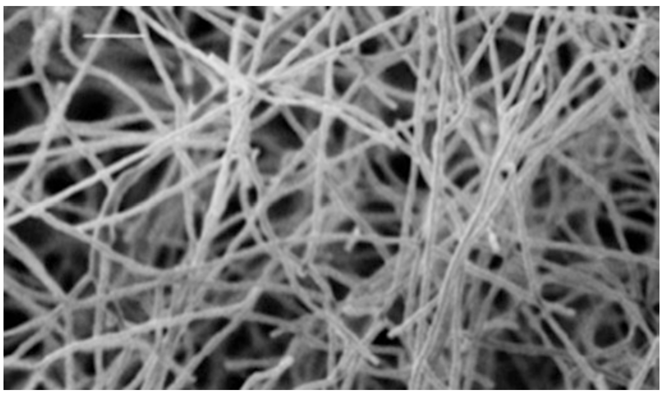

FIGURE 271. Aerial mycelium of *Kribbella swartbergensis*, 14-d-old culture on oatmeal agar (ISP 3). Scanning electron micrograph. Bar = 3 µm. (Reproduced with permission from Kirby et al., 2006. Int. J. Syst. Evol. Microbiol. *56*: 1097–1101.)

The aerial mycelium, if present, is mostly white or pale yellow and consists of straight or curved branched hyphae (Figure 270 and Figure 271). Well-developed and extensively branching substrate mycelium is typically white, off-white, pale yellow, cream, or rarely orange (Table 225). Both the aerial and substrate hyphae, depending on the individual organism and the consistency and composition of growth medium, undergo various degrees of fragmentation to yield nonmotile elongated, Y-shaped, and irregular rod-like elements with square ends (Figure 272, Figure 273, and Figure 274). Shorter fragments often become rounded-off and have the appearance of arthrospores at maturation. Hyphae in many areas may remain stable and not fragmented *in situ* on agar or in liquid media. Short chains of well-to-poorly differentiated conidia can be observed on aerial hyphae. Some organisms may produce bud-like cells on substrate hyphae (Figure 274). Hyphae of many organisms have a tendency to form apical swellings (Lee et al., 2000; recent observation of the authors of this chapter). Spherical or irregularly-shaped structures (up to 3–5 µm in diameter) can be produced on substrate hyphae of some organisms, most abundantly on agar media rich in organics when aerial mycelium is absent (recent observations). These consist of tightly packed, irregularly sized polymorphic cells remaining closely associated with each other after cell division and embedded in a common matrix of extracellular polysaccharide-like material. Both the hyphal fragments (arthrospores) and the cells produced by different division modes usually give rise to new vegetative hyphae when transferred to a fresh medium.

Growth may be pasty, sand-pasty, soft-leathery, or leathery, depending on species, growth media, and growth phase. Diffusible pigments are usually absent, except for melanoid pigments, which are produced on tyrosine agar (ISP 7 medium*) (Table 225) and occasionally on peptone-yeast extract agar (ISP 6 medium). The cell-wall architecture of *Kribbella* species is typical of Gram-positive bacteria (recent observation), but the Gram-staining test may show variable results (Park et al., 1999).

Chemotaxonomy. All *Kribbella* species are characterized by the presence of LL-diaminopimelic acid (LL-A_2pm) as the diamino acid in the cell wall. The peptidoglycan type is A3γ according to classification of Schleifer and Kandler (1972), as follows from the peptidoglycan amino acid composition [alanine, LL-2,6-diaminopimelic acid (LL-A_2pm), glutamic acid, and glycine] of the total cell-wall hydrolysate, and specific dipeptides (L-Ala–D-Glu, LL-A_2pm–D-Ala and LL-A_2pm–Gly) found in the partial cell-wall hydrolysate of *Kribbella lupini* (Trujillo et al., 2006). The monomeric unit of the A3γ polymer type contains L-alanine in the first position and LL-A_2pm in the third position of the tetrapeptide subunit, with a single glycine residue as an interpeptide bridge. The same peptidoglycan amino acids were reported for *Kribbella flavida*, *Kribbella sandramycini* (Park et al., 1999), *Kribbella koreensis* (Lee et al., 2000), *Kribbella solani*, *Kribbella jejuensis* (Song et al., 2004), and *Kribbella ginsengisoli* (Cui et al., 2010); Park et al. (1999) indicated the presence of both D- and L-alanine for *Kribbella flavida* and *Kribbella sandramycini*.

The sugar patterns determined in the cell walls or whole organisms of the recognized *Kribbella* species include combinations of galactose, glucose, mannose, ribose, xylose, and

*See Shirling and Gottlieb (1966) for the composition of ISP media cited here and in other sections of this chapter.

[a]Based on characteristics of the type strains, except for *Kribbella aluminosa*, *Kribbella catacumbae*, and *Kribbella sancticallisti*. Symbols and abbreviations: +, positive; −, negative; w, weakly positive or delayed; v, variable among experiments or methods used (sometimes because of weak growth or reaction); Glc, glucose; Gal, galactose; Man, mannose; Rib, ribose; Xyl, xylose, US1 and US2, unidentified sugars; PC, phosphatidylcholine; PG, phosphatidylglycerol; DPG, diphosphatidylglycerol; PI, phosphatidylinositol; nr, Not reported.

[b]Data from: Park et al. (1999), Lee et al. (2000), Sohn et al. (2003), Song et al. (2004), Li et al. (2004, 2006), Kirby et al. (2006), Trujillo et al. (2006), Carlsohn et al. (2007), Urzì et al. (2008), Everest and Meyers (2008), and Cui et al. (2010).

[c]According to the original descriptions; color may slightly change depending on the growth medium and the culture age.

[d]Dark orange in old colonies on Luedemann medium (Luedemann, 1968).

[e]Obtained on ATCC Medium No. 172 (Cote et al., 1984) according to Kirby et al. (2006) and Everest and Meyers (2008).

[f]Tested on VL agar (Tiecco, 1975) according to Urzì et al. (2008).

[g]Tested on solidified or/and in liquid media of different composition (see the text for details).

[h]Obtained on nutrient agar as basal medium (Trujillo et al., 2006); no growth on ISP 2 as basal medium (Kirby et al., 2006).

[i]Different results reported (Carlsohn et al., 2007; Kirby et al., 2006; Song et al., 2004) are likely influenced by different test conditions.

[j]ISP 9 (Shirling and Gottlieb, 1966) as basal medium, except for *Kribbella ginsengisoli* tested on a minimal salts medium with vitamins and microelements, or using the API API 20NE and ID 32GN test systems (Cui et al., 2010).

[k]See the original species description for test methods.

[l]Determined in whole cells or purified cell walls. Cui et al. (2010) reported glucosamine instead of glucose for *Kribbella flavida, Kribbella koreensis, Kribbella sandramycini* and *Kribbella yunnanensis*, and mannose instead of glucose for *Kribbella alba* and *Kribbella antibiotica*.

[m]Unidentified phospholipids and glycolipids reported in addition (Carlsohn et al., 2007; Urzì et al., 2008).

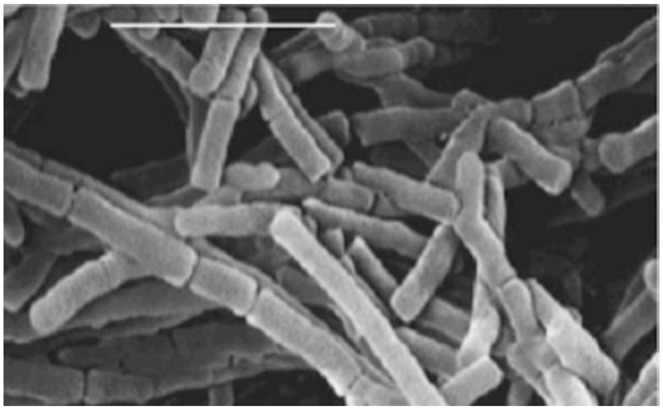

FIGURE 272. Fragmented aerial mycelium of *Kribbella koreensis*, 14-d-old culture on inorganic salts/starch agar (ISP medium 4). Scanning electron micrograph. Bar = 2 μm. (Reproduced with permission from Lee et al., 2000. Int. J. Syst. Evol. Microbiol. *50*: 191–199.)

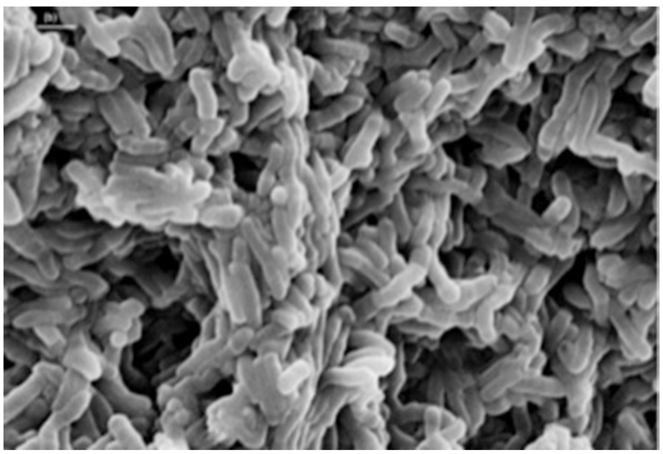

FIGURE 273. Fragmented substrate mycelium of *Kribbella karoonensis*, 14-d-old culture on oatmeal agar (ISP 3 medium). Samples were prepared by placing agar blocks containing substrate mycelium in liquid nitrogen and freezing prior to viewing by cryo-SEM. Bar = 3 μm. (Reproduced with permission from Kirby et al., 2006. Int. J. Syst. Evol. Microbiol. *56*: 1097–1101.)

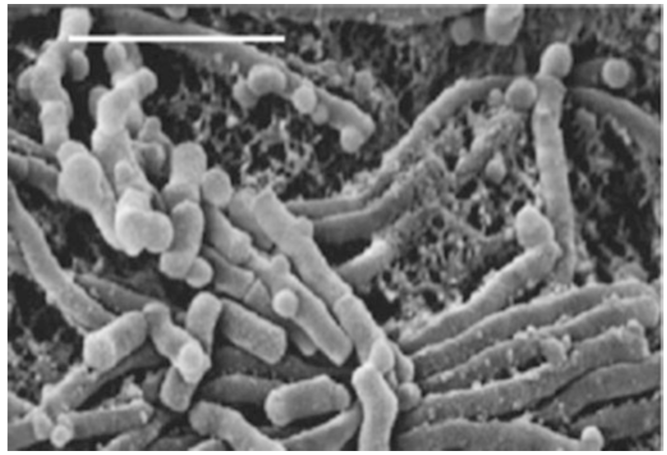

FIGURE 274. Irregularly fragmented substrate mycelium of *Kribbella koreensis* with bud-like cells, 14-d-old culture on inorganic salts/starch agar (ISP medium 4). Scanning electron micrograph. Bar = 2 μm. (Reproduced with permission from Lee et al., 2000. Int. J. Syst. Evol. Microbiol. *50*: 191–199.)

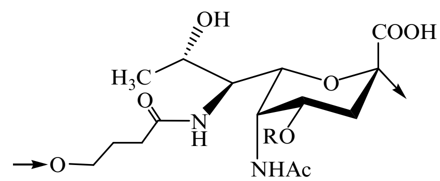

FIGURE 275. Repeating unit of teichulosonic acid of strain *Kribbella* sp. VKM Ac-2541, where R = H (45%), α-D-Gal*p*3OMe (37%) or α-D-Gal*p*2,3OMe (18%).

unidentified sugars (Table 225). In addition, 3-*O*-methyl-D-galactose (madurose), 2,3-di-*O*-methyl-D-galactose, and rhamnose were found in several recently analyzed *Kribbella* strains which supposedly (based on 16S rRNA gene sequence analysis and phenotypic traits) represent at least four novel species (Shashkov et al., 2009; E.M. Tul'skaya and L.I. Evtushenko, unpublished results). In traditional terms (Lechevalier and Lechevalier, 1970), neither individual cell-wall sugars nor sugar pattern are characteristic of all organisms of the genus *Kribbella*. However, the sugars, along with other compounds derived from the cell-wall polysaccharides linked to the peptidoglycan, can serve as chemical markers of individual species or species groups within the genus. Recent studies performed with six of the aforementioned novel *Kribbella* strains revealed that each strain contained two cell-wall polysaccharides, i.e. an acidic phosphate-less polymer as the predominant one and a neutral polysaccharide, a mannan, found in minor or trace amounts (Shashkov et al., 2009; Tul'skaya, 2009). Notably, the mannan (the basic chain built of 1–6-linked α-mannopyranose substituted at O-2 with α-mannopyranose) was common to all six strains studied. The predominant acidic polymers, in contrast, differed to a greater or lesser extent, and were represented either by different teichuronic acids (Ward, 1981) or unusual polysaccharides, the so-called teichulosonic acids (polymers with nonulosonic acids; Knirel, 2009; Knirel et al., 1987, 2003). The disaccharide subunits of the two identified teichuronic acids consisted of aminomannuronic acid and a rare sugar, 2,3-diacetamido-2,3-dideoxy-α-glucopyranose (strain VKM Ac-2539), or of the same sugar and diaminomannuronic acid (strains VKM Ac-2538 and VKM Ac-2540). The subunit of teichulosonic acid of strain VKM Ac-2541 contained in the basic chain a residue of oxybutyrate and pseudaminic acid, a sialic acid-like nine-carbon compound (5,7-diacylamido-3,5,7,9-tetradeoxy-L-glycero-β-L-manno-nonulosonic acid; Knirel et al., 2003; Vimr et al., 2004) with madurose and 2,3-di-*O*-methyl-D-galactose as irregular substituents at O-4 (Figure 275). The teichulosonic acids of the two other strains had the same structure as in strain VKM Ac-2541 plus rhamnose as an additional substituent, or the polymer subunit contained additional galactose (unknown position). Remarkably, neither teichoic acids nor other related phosphorous-containing polysaccharides have been revealed in the cell walls of more than 15 *Kribbella* strains examined up to now (Shashkov et al., 2009; E.M. Tul'skaya, A.S. Shashkov, and L.I. Evtushenko, unpublished), in contrast to organisms of the genera *Nocardioides* and *Aeromicrobium* (Naumova et al., 2001; Takeuchi and Yokota, 1989; Tul'skaya, 2009). Also, although

pseudaminic acid (or its derivatives) is common in capsular polysaccharides, lipopolysaccarides, pili, and flagella of many Gram-negative bacteria (see, e.g. Knirel, 2009; Knirel et al., 1987, 2003; Schoenhofen et al., 2006; Vimr et al., 2004), it has not been found until recently in Gram-positive bacteria except kribbellae.

The predominant menaquinone is MK-9(H_4) in all bacteria of the genus *Kribbella* (Table 226) and may represent up to 93% of the total quinone content as reported for *Kribella aluminosa* (Carlsohn et al., 2007), or even more. The cellular fatty acids of *Kribbella* species are dominated by the saturated iso- and anteiso branched acids, mainly $C_{15:0}$ anteiso, $C_{16:0}$ iso, and $C_{15:0}$ iso. Among these, $C_{15:0}$ anteiso was the predominant component in all species (usually contributing about 30%), except *Kribbella sancticallisti* and *Kribbella swartbergensis* which were reported to contain $C_{16:0}$ iso in maximal proportions (~24–27%) (Carlsohn et al., 2007; Urzì et al., 2008). Monounsaturated *iso*-branched (mostly $C_{17:1}$ iso) as well as saturated 9-methyl branched (mostly 9-methyl-$C_{16:0}$) fatty acids typically occur and may reach 10% or more of the total fatty acids. Other components, including 2-hydroxy (mostly $C_{16:0}$ iso 2-OH) and 10-methyl branched acids ($C_{18:0}$ 10-methyl and $C_{17:0}$ 10-methyl) were reported for some species in minor amounts. Notably, the qualitative and quantitative compositions of fatty acids in strains of this genus may depend on the growth conditions, the culture age, and analytical procedure employed, as demonstrated, e.g. for *Kribbella flavida* and *Kribbella sandramycini* (Park et al., 1999; Sohn et al., 2003; Song et al., 2004; Trujillo et al., 2006).

The principal phospholipids of most *Kribbella* species include PC, DPG, PG, and PI. PG was not reported in *Kribbella jejuensis* and *Kribbella solani* (Song et al., 2004), while PI was not mentioned among main polar lipids of *Kribbella yunnanensis* (Li et al., 2006). On the other hand, an additional phospholipid (tentatively identified as phosphatidylinositol containing 2-hydroxy fatty acids) and some unidentified minor phospholipids occur in all 15 yet-unnamed *Kribbella* strains analyzed (N.G. Vinokurova and L.I. Evtushenko, unpublished data). In addition, one to three glycolipids may present in lesser but significant amounts in *Kribbella* strains, together with a variety of minor or trace amounts of unidentified phospho-, glyco-, and other kinds of polar lipids (Figure 263 in the chapter Genus *Nocardioides*).The clearly detectable glycolipids have chromatographic mobility close to that of PC and DPG. Several unknown minor phospho- and glycolipids, along with PC, DPG, PG, and PI, were also reported for *Kribbella aluminosa* (Carlsohn et al., 2007), *Kribbella catacumbae*, and *Kribbella sancticallisti* (Urzì et al., 2008).

Nutrition and growth conditions. The *Kribbella* strains usually grow well under aerobic conditions at neutral pH or mildly alkaline pH on standard laboratory media, including the chemically defined media, e.g. ISP media used to culture streptomycetes. Kribbellae also utilize a wide range of other organic compounds as carbon sources in ISP9 or other minimal salts media, and possess various enzymatic activities towards complex macromolecules resulting in production of low molecular weight compounds which can be used as carbon (and/or nitrogen) sources (Table 225 and Table 226; see the section *List of species of the genus Kribbella*). *Kribbella ginsengsoli* was reported (Cui et al., 2010) to grow on a minimal medium containing basal salts, a vitamin solution (Widdel and Bak, 1992), trace elements (SL-10; Widdel et al., 1983), selenite/tungstate solution (Tschech and Pfennig, 1984), and a definite carbon source (0.1%). Acids are rather weakly produced by kribbellae under aerobic conditions from carbohydrates as shown for *Kribbella koreensis* (Lee et al., 2000) and some other species. Optimal temperatures for growth vary insignificantly among species, but all organisms of this genus grow well between 25 and 30°C. The higher and lower growth temperatures reported are 45°C (*Kribbella swartbergensis*; Everest and Meyers, 2008) and 8°C (*Kribbella ginsengisoli*; Cui et al., 2010). Members of the genus *Kribbella* usually prefer neutral or slightly alkaline pH for growth. The pH growth range varies with species (Table 225 and Table 226). A few species can grow at initial pH of 5; *Kribbella hippodromi* showed weak growth even at pH 4.3 (Everest and Meyers, 2008). Some species grow at initial pH 10 (*Kribbella catacumbae*, *Kribbella koreensis*, and *Kribbella sancticallisti*; Lee et al., 2000; Urzì et al., 2008). Bacteria of this genus are typically non-halophilic and tolerate low NaCl concentrations; *Kribbella antibiotica* and *Kribbella jejuensis* are the most sensitive to salts (cells grow in 2% NaCl; Carlsohn et al., 2007; Kirby et al., 2006; Song et al., 2004).

It should be noted that actinomycetes of the genus *Kribbella* were originally described as chemo-organotrophs with strictly aerobic metabolism (Lee et al., 2000; Park et al., 1999). However, some species were subsequently shown to grow moderately well (*Kribbella solani*) or weakly (*Kribbella flavida*, *Kribbella jejuensis*, *Kribbella koreensis*, and *Kribbella sandramycini*) on ATCC Medium No. 172* anaerobically in an atmosphere of $H_2/CO_2/N_2$ (5:10:85) (Kirby et al., 2006). According to Urzì et al. (2008), *Kribbella solani* also grew anaerobically on VL agar (Tiecco, 1975). Some yet-unnamed *Kribbella* strains exhibit weak but distinct growth in organic semi-solid medium (0.5% glucose, 0.5% peptone, 0.3% yeast extract, 0.02% K_2HPO_4, 0.3% agar; pH 7.2) under anaerobic and/or microaerophilic conditions; L.M. Baryshnikova and L.I Evtushenko, recent observation). None of the tested kribbellae grew anaerobically on ISP 9 agar with glucose (Kirby et al., 2006). On the other hand, weak aerobic growth was observed for some yet-unnamed *Kribbella* strains on ISP 9 medium without addition of a carbon source (recent observation). *Kribbella koreensis*, when seeded with a diluted soil suspension (during the isolation procedure), showed the ability to grow aerobically on a tap-water agar with antifungal antibiotics (Lee et al., 2000). The data suggest that members of the genus *Kribbella* can adapt to an oligotrophic life style and grow in the presence of traces of carbon and/or nitrogen sources, and probably may scavenge nutrient substances from air, e.g. ammonium. Perhaps, some organisms may even have an autotrophic life style under certain conditions, like that reported or assumed, e.g. for some *Pseudonocardia* and *Streptomyces* (Goodfellow and Lechevalier, 1986; O'Donnell et al., 1993; Selesi et al., 2005; Takamiya and Tubaki, 1956). Recent finding showing that kribbellae increase in numbers in a soil microcosm after hydrogen exposure is indicative of their possible ability to utilize hydrogen as a source of energy (Osborne et al., 2010). All the above data, along with data showing that *Kribbella* often occur in nutrient-limited environments, including acidic and heavy-metal-contaminated ones (see below the section Habitats and ecology), suggest that at least certain organisms of this genus are rather aerobic chemo-organotrophs with a potential for mixotrophy and metabolic flexibility.

* *Hongia* Lee, Kang and Hah 2000, 197[VP] is a later heterotypic synonym of *Kribbella* Park, Yoon, Shin, Suzuki, Kudo, Seino, Kim, Lee and Lee 1999, 750[VP]

[a]See Table 225 for symbols, for references and other details. Data in parentheses (for the pH growth range) indicate variable, weak or delayed growth; w/−, doubtful growth.

[b]9(H_4), menaquinone having nine isoprene units two of which are saturated.

[c]ISP 9 (Shirling and Gottlieb, 1966) as basal medium. See Table 225 for *Kribbella ginsengisoli*; positive results were also obtained for *Kribbella koreensis* in the same study (Cui et al., 2010) with D-glucose, lactose, maltose, D-mannose, D-melibiose, L-rhamnose, and sucrose.

[d]Growth with the listed organic acids as sole carbon sources on basal medium ISP 9 (Shirling and Gottlieb, 1966), unless other methods indicated.

[e]An alkaline reaction, according to the method of Gordon et al. (1974); growth also occurs with acetate, lactate, or malate, but not with citrate (API 20NE; Cui et al., 2010).

Genomic characteristics. The DNA base ratio of species of the genus *Kribbella* ranges from 66.3 mol% (Cui et al., 2010) to 71.3 mol% (Lee et al., 2000), with 70 mol% reported for the type strains of the type species *Kribbella flavida* (Park et al., 1999). As mentioned before, the current 16 *Kribbella* species form a coherent phylogenetic cluster, with some species showing more than 99% 16S rRNA gene sequence similarity. The DNA–DNA similarities between *Kribbella* species obtained by different methods ranged from 0% for the pair *Kribbella koreensis*–*Kribbella sandramycini* (Sohn et al., 2003), which looks rather ambiguous, to 61.2% for *Kribbella yunnanensis*–*Kribbella sandramycini* (Li et al., 2006). Recently, the sequences of *gyrB* gene (encoding the β-subunit of DNA gyrase, a type II DNA topoisomerase) have been analyzed for strains of the 15 recognized *Kribbella* species (Kirby et al., 2010). The type strains of *Kribbella* species had partial *gyrB* gene sequence (1108 nt, 56% of the full-length *gyrB*) similarity values in the range 89.91–94.95%, except for the pair *Kribbella solani*–*Kribbella hippodromi* (98.22%).

The 16S–23S rDNA internally transcribed spacer (ITS) sequences and the ribonuclease P RNA gene sequences were analyzed for *Kribbella flavida* and *Kribbella sandramycini* (Yoon et al., 1998a; Yoon and Park, 2000). The type strain of *Kribbella sandramycini* was reported to contain two types of 16S–23S ITS sequences (*rrn* 1, 429 bp; *rrn* 2, 439 bp) showing high sequence divergence, with the nucleotide similarity level of 80.8% (and 78.4% when gaps are included). The type strain of *Kribbella flavida* exhibits a higher degree of ITS sequence similarity to that of *Kribbella sandramycini* (75.4%, *rrn* 1; 73.6%, *rrn* 2) than to the ITS sequences of representatives of *Nocardioides* and *Aeromicrobium* used in the study. The same *Kribbella* strains shared 92±2% similarity of the ribonuclease P RNA gene sequences and formed a cluster distinct from the strains of other genera analyzed (Yoon and Park, 2000). Gao and Gupta (2005) revealed in *Kribbella sandramycini*, along with an insertion in the 23S rRNA gene, three conserved indels in three widely distributed proteins, i.e. a deletion in cytochrome *c* oxidase subunit 1, an insertion in CTP synthetase, and an insertion in glutamyl-tRNA synthetase that are distinctive characteristics of most *Actinobacteria* and not found in any other groups of bacteria. The phylogenetic analysis based on CTP synthetase sequences showed that the overall topology of the tree of actinobacteria studied was very similar to that seen in the 16S rRNA gene trees. One of the interesting exceptions relevant to this chapter is *Kribbella sandramycini*, which is grouped with *Saccharopolyspora erythrea* DSM 40517 (not with *Nocardioides simplex*) and has an almost identical CTP synthetase sequence to that of *Saccharopolyspora erythrea* DSM 40517 (Gao and Gupta, 2005). Recently, the sequence of the complete genome for *Kribbella flavida* DSM 17836 (a circular chromosome of 7,579,488 nt, 7086 genes with a protein-coding capacity, 60 RNA genes, and 143 predicted pseudogenes) was determined (Pukall et al. 2010, GenBank accession no. NC_013729). The majority of the protein-coding genes (70.7%) were assigned with a putative function while those remaining were annotated as hypothetical proteins).

Antibiotic sensitivity and antibiotic production. Strains of *Kribbella flavida*, *Kribbella antibiotica*, *Kribbella jejuensis*, *Kribbella karoonensis*, *Kribbella koreensis*, *Kribbella sandramycini*, *Kribbella solani*, and *Kribbella swartbergensis* were reported to be sensitive to ampicillin sodium salt (100 μg/ml) and also (except *Kribbella jejuensis*) to cefotaxime (10 μg/ml) (Kirby et al., 2006). Except for *Kribbella solani*, all the above strains, as well as *Kribbella catacumbae* and *Kribbella sancticallisti*, are inhibited by tobramycin (10 μg/ml) (Kirby et al., 2006; Urzì et al., 2008). All the above-mentioned species are resistant to carbenicillin (100 μg/ml) and, except *Kribbella sancticalisti* and *Kribbella ginsengisoli*, and to streptomycin (10 μg/ml) (Cui et al., 2010; Kirby et al., 2006; Urzì et al., 2008). The listed and other members of this genus are sensitive to a wide range of other antibiotics (see the *List of species of the genus Kribbella*). A few *Kribbella* strains were reported to produce biologically active compounds. *Kribbella sandramycini* ATCC 39419 produces an antitumor antibiotic, sandramycin (a cyclic decadepsipeptide with a two-fold axis of symmetry and 3-hydroxyquinaldic acid as an appended chromophore; Matson and Bush, 1989; Matson et al., 1993). *Kribbella koreensis*is produces novel neuropilin/growth factor complexes (Alitalo et al., 2003). *Kribbella antibiotica* possesses antifungal activity (Li et al., 2004) and *Kribbella jejuensis* inhibits growth of *Streptomyces scabiei* (Song et al., 2004).

Habitats and ecology. Kribbellae are widely distributed in terrestrial ecosystems worldwide, mostly in soils of different origin, including acidic ones (Ding et al., GenBank accession no. FJ938352; Zheng and Huang, GenBank accession no. EU697199) and polluted sites (Cho et al., 2006; Leigh et al., 2007). Representatives of *Kribbella* were found in the root zone of an Austrian pine (*Pinus nigra* L.) growing naturally in soil contaminated with polychlorinated biphenyls (PCBs) (Leigh et al., 2007). Furthermore, kribbellae along with *Pseudonocardia*, *Nocardiodes*, and *Sphingomonas* were the predominating representatives of 75 genera which utilized carbon from PCBs (Leigh et al., 2007). Organisms of this genus often occur in sub-subsurface and nutrient-limited environments, including gold-mine caves (Lee et al., 2000), an alum slate mine (Carlsohn et al., 2007), and catacombs (Urzì et al., 2008). Heterotrophic lifestyle and enzymatic activity towards complex macromolecules assume that kribbellae function as consumers of organic material in soil. In environments of nutrient scarcity, they probably use traces of organics dissolved in water or derived from the decomposition of other microorganisms, are involved in mutualistic interactions with other microorganisms, or engage in chemolithotrophic metabolism with input from some atmospheric gases and minerals, like those suggested for other actinomycetes from such environments (Barton et al., 2007; Groth and Saiz-Jimenez, 1999). Organisms of this genus and some other soil bacteria are assumed to be important utilizers of hydrogen at low concentrations in soil, and could be important contributors to the function of soil as a sink in the global hydrogen cycle (Osborne et al., 2010). Kribbellae also occur among microbial endophytes in plant tissues (Conn and Franco, 2004; Trujillo et al., 2006) and in bacterial communities associated with spores of the endomycorrhizal fungus *Gigaspora margarita* (L. Long, H. Zhu, and Q. Yao, GenBank accession no. EU589433). *Kribbella solani* was isolated from a potato tuber with scab lesions (Song et al., 2004), although there is no evidence of its plant pathogenic properties. Representatives of this genus were also found in the bacterial community of human skin (Kong et al., GenBank accession no. HM277981). To the authors' knowledge, kribbellae have not been discovered up to now in marine ecosystems or in clinical specimens. The spores or cells of *Kribbella* are thought to survive or maintain a low metabolic activity under extreme conditions in nature, since these remain alive in a soil sample (from which some species have been isolated) after exposure to temperature as high as 120°C for 1 h (dry heating) (Kirby et al., 2006).

Enrichment and isolation procedures

The available strains of the genus *Kribbella* are mostly random isolates obtained during studies on (actinobacterial) microbiota of certain biotopes or screenings for biologically active compounds. Strains of this genus are normally isolated by plating on suitable "total count" agar media, e.g. R2A agar (Difco), as well as those used for isolation of certain actinomycete groups. Incubation is usually carried out at 25–30°C for a week to a month. Generally, kribbellae relatively frequently occur among the mycelial soil isolates having sand-pasty or soft-leathery, agar-penetrating and non-pigmented, yellowish or light cream colonies developing on R2A agar. Other media, reported in the original species descriptions, e.g. glycerol-asparagine agar (ISP 5 medium), glucose-yeast extract-malt extract (ISP 2 medium), SM1 agar (proposed for isolation of *Amycolatopsis*; Tan et al., 2006), yeast extract-mannitol agar (used for isolation of *Rhizobia*; Vincent, 1970), tap-water agar, etc. were successfully employed for isolation of kribbellae. Various isolation strategies used to isolate mycelial actinomycetes, including air-drying and heating (up to 120°C for 1 h; Kirby et al., 2006) of soil samples, adding antifungal antibiotics, exposition in alkaline solutions, etc., may be used to reduce the numbers or inhibit the growth of accompanying microbes. When intending isolation of strains belonging or closely related to the described *Kribbella* species, some selective (semi-selective) media may be formulated on the basis of characteristics listed in Table 225 and Table 226, and a consideration of the resistance to certain antibiotics and heavy metal salts and the isolation sources.

Maintenance procedures

Cultures may be maintained as 20% glycerol suspensions at −20 and −80°C. Long-term conservation is achieved by freeze-drying or in liquid nitrogen by standard procedures.

Differentiation of the genus *Kribbella* from other genera

The phenotypic characteristics essential for delineation of *Kribbella* from other genera of the family are listed in Table 214. The formation of well-developed branching hyphae allows primary separation of *Kribbella* from the genera *Aeromicrobium*, *Marmoricola*, and the vast majority of *Nocardioides* species. The predominant menaquinone MK-9(H_4) and the presence of phosphatidylcholine among principal polar lipids clearly distinguish kribbellae from all species of the genus *Nocardioides*. The polar lipid pattern containing phosphatidylcholine is also the most distinctive feature that differentiates kribbellae both from the genera of the family *Nocardioidaceae* and other actinomycete genera comprising mycelium-forming organisms with LL-A_2pm in the cell wall. A rapid method based on single-digestion restriction analysis of the PCR-amplified 16S rRNA gene with endonucleases (*Mbo*I, *Vsp*I, *Sph*I, *Sna*BI, *Sal*I, and *Age*I), useful for identification of *Kribbella* strains, is described (Cook and Meyers, 2003).

Taxonomic comments

The genus *Kribbella* was established by Park et al. (1999) with *Kribbella flavida* (type species) and *Kribbella sandramycini* to accommodate two strains, which were previously ascribed to the genus *Nocardioides*, i.e. "*Nocardioides fulvus*" (Ruan and Zhang, 1979) and *Nocardioides* sp. ATCC 39419, a producer of the antibiotic sandramycin (Matson and Bush, 1989). Almost simultaneously, Lee et al. (2000) independently published the description of *Hongia koreensis* for an original isolate which was very close to *Kribbella* at the phylogenetic level and similar in many phenotypic characteristics. Subsequent taxonomic analysis of the above species resulted in the reclassification of *Hongia koreensis* as *Kribbella koreensis* (Sohn et al., 2003). The remaining 13 *Kribbella* species were described within the 2004–2010 period on the basis of taxonomic studies mostly of single environmental isolates. As mentioned before, some species of this genus are very close phylogenetically and share up to 99% or more 16S rRNA gene sequence similarity, with the highest value being between *Kribbella solani* and *Kribbella hippodromi* (99.64%) by local alignment (Everest and Meyers, 2008). The type strains of *Kribbella solani* and *Kribbella hippodromi* also display the closest identity (98.2%) by *gyrB* gene sequence similarity (Kirby et al., 2010). Nevertheless, these two species had a DNA–DNA similarity of approximately 40%, as revealed by hybridization experiments, and differed in a number of phenotypic properties (Everest and Meyers, 2008). Analogously, the DNA–DNA similarity values between the type strains of other phylogenetically very close species (see Cui et al., 2010, and Kirby et al., 2010, for details and references) are below the threshold value of 70% recommended for the definition of bacterial species (Wayne et al., 1987).

Differentiation of species of the genus *Kribbella*

The phenotypic properties useful in preliminarily distinguishing of *Kribbella* species are listed in Table 225. Additional differentiating and descriptive characteristics are given in Table 226 and outlined in the descriptions of species. It is worth noting that the available differential physiological and biochemical characteristics are based, in most cases, on the data obtained for a single representative of a species. Moreover, conflicting results have been reported for strains which give rather weak or doubtful growth on some carbon sources and showed very weak activities in degradation tests. Some differences in salt resistance and the pH growth range of a strain can be influenced by the test medium composition (Carlsohn et al., 2007; Cui et al., 2010; Kirby et al., 2006; Song et al., 2004; Trujillo et al., 2006). Chemotaxonomic features such as the composition of cell-wall sugars, polar lipids, and fatty acid profiles are important for differentiation purposes. It should be emphasized that whole cells but not cell walls were analyzed in most *Kribbella* species or the purified cell walls were obtained (and analyzed) by different methods, and this should be taken into account when comparing the sugar composition. Also the qualitative and quantitative compositions of fatty acids (and polar lipids) in strains of this genus may be influenced by growth conditions and analytical procedures. For the comparison of fatty acid profiles, the data should therefore be obtained solely by growing cells under standardized cultivation conditions and performing analyses in the same laboratory rather than from the literature. The distance dendrogram generated on the basis of fatty acid profiles by the software of the Sherlock Microbial Identification System may be useful to separate strains of phylogenetically related species (Urzì et al., 2008). Matrix Assisted Laser Desorption Ionization Time-of-Flight (MALDI/TOF) mass spectrometry of proteins and the RiboPrint analyses (with *Pvu*II as the restriction enzyme) are also quite helpful for clustering of phylogenetically close *Kribbella* strains at the strain-species level (Carlsohn et al., 2007; Urzì et al., 2008).

DNA–DNA hybridization studies may be necessary to support the species affiliation of a strain or strain group which is closely related to known species on the basis of 16S rRNA gene sequences or other characteristics. Analysis of *gyrB* gene sequences is advantageous to assess membership of a strain in question to an established species. According to Kirby et al. (2010), strains with *gyrB*-based genetic distance exceeding 0.04 to a known species (calculated from partial *gyrB* gene sequences, 1108 nt) most likely represent a distinct species. This value therefore is suggested as a cut-off point to determine whether DNA-DNA hybridization is required. A 390-nucleotide sequence of the *gyrB* gene (a variable region from 1010 to 1400 bp according to *Streptomyces avermitilis* MA-4680 *gyrB* numbering) is sufficient to preliminarily assess whether a strain is likely to represent a new species. The GenBank numbers for the *gyrB* gene sequences of *Kribbella* strains, PCR primers for amplification of the *Kribbella gyrB* gene, and the details of the method are available from Kirby et al. (2010).

List of species of the genus *Kribbella*

1. **Kribbella flavida** Park, Yoon, Shin, Suzuki, Kudo, Seino, Kim, Lee and Lee 1999, 750[VP]

fla′vi.da. L. fem. adj. *flavida* yellowish, pale yellow.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Park et al., 1999), unless indicated.

Substrate mycelium is usually pale yellow and consists of extensively branched hyphae penetrating into agar media and often fragmenting into rod-shaped to coccoid elements. Aerial hyphae appear straight or curved and break up into short to elongated rod-like fragments (Figure 270). Colonies are usually pasty and have lichenous shapes. Melanin is produced on ISP 7 medium. Gram-staining reaction is variable. Grows at 12–30°C and at pH 9 (initial pH value of test media); growth at 37°C and at pH 5 varies with experiments (Kirby et al., 2006; Park et al., 1999; Trujillo et al., 2006). Grows at 3% NaCl on nutrient agar (Trujillo et al., 2006) but not on ISP 2 medium supplemented with the same salt concentration (Kirby et al., 2006). Produces pyrrolidonyl arylamidase (API ZYM; Trujillo et al., 2006).

Grows in the presence (µg/ml) of carbenicillin disodium salt (100), cephaloridine (10), chloramphenicol (50), cycloheximide (10), erythromycin (10), gentamycin sulfate (10, weak), and streptomycin sulfate (10). Growth is inhibited by ampicillin sodium salt (100 mg/ml), cefotaxime (10), neomycin sulfate (10), tobramycin sulfate (10), and vancomycin hydrochloride (10) (Kirby et al., 2006). The major fatty acids (>5% of the total registered at least in one experiment) reported for cultures grown under different conditions were $C_{15:0}$ anteiso (24.9–32), $C_{16:0}$ iso (14.0–21.3), $C_{16:1}$ iso (2–13.5), $C_{17:0}$ anteiso (3.2–10.0), $C_{14:0}$ iso (3–9.1), $C_{15:0}$ iso (5.0–5.4), $C_{17:1}$ iso ω9*c* (< 1–6.7), 9-methyl-$C_{16:0}$ (< 1–8) (Park et al., 1999; Sohn et al., 2003; Song et al., 2004), $C_{17:1}$ ω8*c* (10.6) (Song et al., 2004), and $C_{17:1}$ ω9*c* (7.0) (Sohn et al., 2003).

Source (type strain): soil near Beijing, China.

DNA G+C content (mol%): 70 (HPLC); 70.6% (calculated for the genome; Pukall et al., 2010).

Type strain: DSM 17836, KACC 20248, KCTC 9580, IFO (now NBRC) 14399, JCM 10339.

Sequence accession no. (16S rRNA gene): AY253863, AF005017.

Sequence accession no. (complete genome): NC_013729.

2. **Kribbella alba** Li, Wang, Zhang, Xu and Jiang 2006a, 1459[VP] (Effective publication: Li, Wang, Zhang, Xu and Jiang 2006b, 34.)

al′ba. L. fem. adj. *alba* white.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Li et al., 2006).

Substrate mycelium ranges from pale yellow on ISP 3, ISP 4, Czapek's agar, and potato agar to soft yellow on ISP 2 and nutrient agar. The hyphae are extensively branched and often fragment into irregular rod-shaped elements. Aerial mycelium is developed on all the media tested, and it is white (on ISP 3, 4, and 5 media and on potato agar), yellow-white (on ISP 2 and Czapek's agar) or pale yellow (on nutrient agar). Some areas of aerial hyphae fragment into short to elongated rod-like elements which can be arranged in chains. The major fatty acids (> 5% of the total) determined in cells grown on TSA at 28°C include $C_{15:0}$ anteiso (27.9), $C_{16:0}$ iso (15.3), $C_{15:0}$ iso (9.1), $C_{17:1}$ iso ω9*c* (10.4), and $C_{17:0}$ anteiso (6.1).

Source: soil in Yunnan Province, the west of China.

DNA G+C content (mol%): 67.9 (T_m).

Type strain: YIM 31075, CCTCC AA 001020, DSM 15500, JCM 14306, NBRC 103561.

Sequence accession no. (16S rRNA gene): AY082062.

3. **Kribbella aluminosa** Carlsohn, Groth, Spröer, Schütze, Saluz, Munder and Stackebrandt, 2007, 1946[VP]

a.lu.mi.no′sa. L. fem. adj. *aluminosa* aluminous, foil of alum, alum-containing, referring to the source of isolation of the first strains.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Carlsohn et al., 2007).

Extensively branched, beige to pale yellow substrate mycelium is produced on all media tested. White aerial mycelium varies in abundance and typically forms well on ISP 5 medium and less abundantly on ISP media 2, 3, and 4, but not on organic medium 79 (Prauser and Falta, 1968). Both vegetative and aerial hyphae fragment into irregular rod-shaped elements. Colonies on organic medium 79 are wrinkled and of a pasty consistency. Grows at 20 and 37°C; no growth occurs at 6 or 42°C. No growth is also observed

at pH 4.5 or 9.0 (initial pH values of liquid organic medium 79). Grows in the same medium with 2% NaCl but not with 4% NaCl. Growth occurs on minimal agar medium (Amoroso et al., 2000) in the presence of $NiCl_2$ (5.0 mM) or $CuSO_4$ (0.5 mM). Aconitate (delayed) is utilized as a sole carbon source, but benzoate and DL-tartrate are not. In API ZYM tests, positive reactions are observed for leucine arylamidase, valine arylamidase, α-galactosidase, α-glucosidase, β-glucosidase, esterase lipase (C8), α-mannosidase, *N*-acetyl-β-glucosaminidase, acid phosphatase, and alkaline phosphatase, but not β-glucuronidase or trypsin; weak or negative reaction for α-chymotrypsin. Hippurate is hydrolyzed. Indole is not produced. Susceptible to the following antibiotics (μg per disc): ampicillin (10), chloramphenicol (30), ciprofloxacin (5, weakly), imipenem (10), novobiocin (5, weakly), ofloxacin (10, weakly), oxytetracycline hydrochloride (30, weakly), as well as polymyxin B (300 IU per disc, weakly). Resistant to (μg per disc) lincomycin hydrochloride (2), methicillin (5), nalidixic acid (30), norfloxacin (10), and penicillin G (10 IU per disc). The major fatty acid (>5% of the total registered at least for one strain) as determined in three strains grown at 28°C in tryptic soy broth (TSB; Sigma-Aldrich) and harvested at exponential growth phase include $C_{15:0}$ anteiso (36.0–44.6), $C_{16:0}$ iso (7.5–17.6), $C_{15:0}$ iso (6.1–9.7), $C_{14:0}$ iso (2.7–6.1), $C_{17:0}$ anteiso (4.6–5.4), and 9-methyl-$C_{16:0}$ (7.0–8.7).

Source: acidic and heavy-metal-containing rock surfaces, a medieval alum slate mine in Thuringia, Germany.

DNA G+C content (mol%): not determined.

Type strain: HKI 0478, DSM 18824, JCM 14599.

Sequence accession no. (16S rRNA gene): EF126967.

4. **Kribbella antibiotica** Li, Wang, Zhang, Schumann, Stackebrandt, Xu and Jiang 2004a, 1425[VP] (Effective publication: Li, Wang, Zhang, Schumann, Stackebrandt, Xu and Jiang 2004b, 164.)

an.ti.bio′ti.ca. Gr. prep. *anti* against, in opposition to; Gr. n. *bios* life; L. suff. *-icus -a -um*, suffix used in adjectives with the sense of belonging to, related to; N.L. fem. adj. *antibiotica* related to antibiotic (the type strain of *Kribbella antibiotica* is an antifungal strain).

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Li et al., 2004b), unless indicated.

Substrate mycelium is yellow white (on ISP 3, 4, and 5 media) or yellow (on potato agar), extensively branched, and often fragments into irregular rod-shaped elements. Aerial mycelium is developed on all the media tested, particularly on Czapek's agar and ISP 5 medium, and fragments into elongated to short rod-like elements. The color of aerial mycelium is yellow white on ISP 3, ISP 4, ISP 5, Czapek's agar, and nutrient agar, soft yellow on ISP 2, and gray yellow on potato agar. Melanin is produced on ISP 7 medium. Grows at 22–30°C. No growth occurs at 12 or 37°C (Trujillo et al., 2006). This species does not grow on ISP 2 medium supplemented with 2% NaCl (Kirby et al., 2006). Grows in the presence (μg/ml) of carbenicillin disodium salt (100), cephaloridine (10), chloramphenicol (20, weak), cycloheximide (10), streptomycin sulfate (10), and vancomycin hydrochloride (10) but not in the presence of ampicillin sodium salt (100), cefotaxime (10), chloramphenicol (50), erythromycin (10), gentamycin sulfate (10), neomycin sulfate (10), and tobramycin sulfate (10) (Kirby et al., 2006). Produces a substance with antifungal activity. The predominant fatty acids determined in cells grown in liquid ISP 2 medium at 28°C were $C_{15:0}$ anteiso and $C_{15:0}$ iso.

Source (type strain): soil in Yunnan Province, China.

DNA G+C content (mol%): 67 (T_m).

Type strain: YIM 31530, CCTCC AA 001021, DSM 15501, JCM 13523, NBRC 101882.

Sequence accession no. (16S rRNA gene): AY082063.

5. **Kribbella catacumbae** Urzì, De Leo and Schumann 2008, 2095[VP]

ca.ta.cum′ba.e. L. gen. n. *catacumbae* of a catacomb, isolated from a Roman catacomb.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Urzì et al., 2008).

Substrate hyphae (diameter 0.36 μm) are branched and tend to penetrate into the agar. They are pale yellow to orange-yellow on the test media, becoming dark orange in old cultures on Luedemann medium [0.5% yeast extract (Difco), 0.5% NZ Amine type A (Sheffield Chemical Co., Norwich, NY), 1% glucose, 2% soluble starch (Difco), 0.1% $CaCO_3$, and 1.5% agar (Luedemann, 1968)]. Colonies are irregular (diameter 5–10 mm), with lobate margin, crateriform profile and rough surface, that are covered with white aerial hyphae. No distinct formation of rod-shaped elements due to fragmentation has been observed in cultures on Luedemann medium, but morphological structures resembling short chains of non-separated arthrospores are observable by electron microscopy. Melanin is produced on ISP 7 medium. Grows at 15–30°C; weak growth is observed at 10°C. Grows in the presence of 2% NaCl and weakly at 3%, but not at 5% as determined on Luedeman agar without $CaCO_3$ addition. Grows at pH 5–9, with weak growth at pH 10 (initial pH values of the same medium). Weak growth on D-raffinose and sorbitol after 21 d. Tweens 20, 40, and 60 are hydrolyzed, and DNA is weakly hydrolyzed. Resistant to the following antibiotics (μg/ml): cephaloridine (10), neomycin sulfate (1.5), streptomycin sulfate (10), and vancomycin hydrochloride (10). Growth is inhibited by chloramphenicol (50), gentamycin sulfate (3), and tobramycin sulfate (1.5). Sensitive to 0.01% lysozyme. Major fatty acids (>10% of the total) as determined for 6 strains grown on TSA at 28°C for 24 h were $C_{15:0}$ anteiso (22.4–28.3), $C_{15:0}$ iso (20.5–28.7), and $C_{17:1}$ iso ω9*c* (9.9–10.6).

Source: deteriorated surfaces in the St. Callistus catacombs, Rome, Italy.

DNA G+C content (mol%): not determined.

Type strain: BC631, DSM 19601, JCM 14968.

Sequence accession no. (16S rRNA gene): AM778575.

6. **Kribbella ginsengisoli** Cui, Lee, Lee and Im 2010, 366[VP]

gin.sen.gi.so′li. N.L. n. *ginsengum* ginseng; L. n. *solum* soil; N.L. gen. n. *ginsengisoli* of soil of a ginseng field.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Cui et al., 2010).

Extensively branched substrate mycelium penetrating into the agar and aerial mycelium are observed on R2A agar plates (Difco) and most other media tested. Cells are not lyzed in the KOH test according to the method of Buck (1982). Grows at 8–37°C but not at 6 or 42°C. Will grow on R2A agar with up to 4.0% NaCl, and in the pH range of 5.5–8.5. Grows on nutrient agar (Difco) but not on MacConkey agar. Unable to reduce nitrate or nitrite under either aerobic or anaerobic conditions. Utilizes glucose as a sole carbon source but does not produce acid or gas from it (API 20NE and ID 32GN tests systems). In addition to compounds listed in Table 225 and Table 226, the following carbon sources are utilized: amygdalin, asparagine, aspartate, fumarate, gluconate, glutamate, glutamine, glycogen, L-histidine, oxalate, phenylalanine, pyruvate, threonine, and valerate; the following compounds are not utilized as sole carbon sources: adipate, L-alanine, arginine, benzoic acid, 3- and 4-hydroxybenzoates, caprate, cysteine, dextran, dulcitol, ethanol, formic acid, D-fucose, glutarate, glycine, isoleucine, itaconate, leucine, lysine, D-lyxose, maleic acid, malonate, methanol, methionine, phenyl acetate, proline, propionate, D-rhamnose, D-ribose, salicin, L-serine, L-sorbose, suberate, tartarate, tryptophan, tyrosine, valine, or xylitol (conventional method with minimal salts medium containing vitamins and microelements, and/or the API 20NE and ID 32GN test systems). Negative for production of arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, and tryptophan deaminase. Degrades chitin, but not DNA. Indole is not produced from tryptophan. Voges–Proskauer test is positive. Growth is inhibited by the following antibiotics (μg per disc): streptomycin sulfate (6), gentamycin sulfate (4), tetracycline hydrochloride (10), chloramphenicol (15), kanamycin (6), penicillin (18), or erythromycin (6). The major fatty acids (5% or more), as determined for cells grown in tryptic soy broth for 5 d at 30°C include $C_{15:0}$ anteiso (20.6), $C_{16:0}$ iso (11.5), $C_{16:0}$ (8.8), $C_{16:0}$ 2-OH (8.1), $C_{15:0}$ iso (6.4), $C_{17:0}$ iso (5.0), and $C_{18:0}$ (6.3).

Source (type strain): soil from of a ginseng field, Pocheon Province, South Korea.

DNA G+C content (mol%): 66.3 (HPLC).

Type strain: Gsoil 001, KCTC 19134, DSM 17941.

Sequence accession no. (16S rRNA gene): AB245391.

7. **Kribbella hippodromi** Everest and Meyers, 2008, 444[VP]

hip.po.dro′mi. Gr. masc. n. *hippodromos* horse racecourse, N.L. gen. masc. n. *hippodromi* of/from a horse racecourse, referring to the source of isolation of the type strain, Kenilworth Racecourse, Cape Town, Western Cape, South Africa.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Everest and Meyers, 2008).

Substrate mycelium is usually cream-colored, with extensively branched hyphae, which fragment in both liquid and agar cultures. Aerial mycelium is white on ISP 4 medium. Colonies appear convoluted with irregular edges on most media. Grows at 20–37°C, but not at 45°C. Growth occurs in the presence of 5% NaCl, with very weak growth at 6% NaCl, and no growth at 7% NaCl (tested on ISP 2 medium). Grows weakly at pH 4.3 (initial pH value of Bennett's agar). Utilizes salicin as a sole carbon source. Utilizes L-arginine, L-asparagine, L-histidine, L-threonine, and nitrate as sole nitrogen sources, with weak growth on L-cysteine and L-serine. Gives also weak growth on DL-α-amino-*n*-butyric acid, L-4-hydroxyproline, and L-valine as sole nitrogen sources and no growth on L-methionine and L-phenylalanine (characteristics distinguishing this species from *Kribbella solani* which shows clear growth on these amino acids). Allantoin, guanine, and pectin are not degraded or hydrolyzed. Resistant to the following antibiotics (μg/ml): lincomycin hydrochloride (100), neomycin sulfate (50), oleandomycin phosphate (100), rifampicin (50), streptomycin sulfate (100), and penicillin G (10 IU /ml). Sensitive to (μg/ ml) cephaloridine (100), tobramycin sulfate (50), and vancomycin hydrochloride (50). No antibacterial activity against *Mycobacterium aurum*.

Source (type strain): soil sample from a fynbos-rich site, Kenilworth Racecourse, Cape Town, South Africa.

DNA G+C content (mol%): not determined.

Type strain: S1.4, DSM 19227, JCM 15572, NRRL B-24553.

Sequence accession no. (16S rRNA gene): EF472955.

8. **Kribbella jejuensis** Song, Kim, Hong, Cho, Sohn, Chun, Sun, 2004, 1347[VP]

je.ju.en′sis. N.L. fem. adj. *jejuensis* of or belonging to Jeju, Korea.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Song et al., 2004), unless indicated.

Substrate mycelium is usually cream-colored and consists of broadly branched hyphae. Aerial hyphae are white and fragmenting into rod-shaped elements. Colonies are usually sand-pasty and have lichenous shapes. Grows at 28–30 and 42°C (Carlsohn et al., 2007; Song et al., 2004) and in the presence of 2% NaCl on ISP 2 medium (Kirby et al., 2006); no growth is observed (Carlsohn et al., 2007) in liquid organic medium 79 (Prauser and Falta, 1968) at the same salt concentration. No growth occurs at initial pH 5 or pH 9 as assessed both on Bennet's agar and in liquid organic medium 79 (Carlsohn et al., 2007; Kirby et al., 2006). Utilizes DL-arginine, L-histidine, DL-homoserine, DL-α-amino-*n*-butyric acid, *trans*-4-hydroxy-L-proline, ammonium, and nitrate as nitrogen sources. Does not utilize salicin as a sole carbon source. Hydrolyzes tributyrin. Does not decompose guanine, allantoin, and chitin. Produces trypsin (Carlsohn et al., 2007). Tolerant to 0.01% (w/v) lysozyme, 0.1% (w/v) phenyl ethanol, and 0.001% (w/v) potassium tellurite, but not to 0.01% (w/v) sodium azide, 0.01% (w/v) thallous acetate, or 0.1% (w/v) phenol. Grows in the presence (μg/ml) of carbenicillin disodium salt (100), cefotaxime (10), chloramphenicol (50), cycloheximide (10), erythromycin (10), gentamycin (0.4), neomycin sulfate (10, weak), rifampicin (4), streptomycin sulfate (10), tetracycline (1), tobramycin (4, weak), and vancomycin hydrochloride (10) but not in the presence of ampicillin sodium salt (100), cephaloridine (10), gentamycin sulfate (10), streptomycin (20), tobramycin sulfate (10), and troleandomycin (10) (Kirby et al., 2006; Song et al., 2004). Weak growth occurs

in the presence of penicillin G (10 U/ml). Carlsohn et al. (2007) reported that the type strain of this species resisted ampicillin (10 µg per disk) and imipenem (10 µg per disk). Shows weak antimicrobial activity towards *Streptomyces scabiei* but not against *Bacillus subtilis*, *Pseudomonas aeruginosa*, *Micrococcus luteus*, *Candida albicans*, *Aspergillus niger*, *Trichoderma harzianum*, *Fusarium acuminatum*, and *Colletotrichum gloeosporioides*. The major fatty acids (>5% of the total) determined for the cultures grown on TSA (BBL) at 30°C (Song et al., 2004) and in TSB at 28°C and harvested at the logarithmic growth phase (Carlsohn et al., 2007) were similar: $C_{15:0}$ anteiso (31.2 and 27.1), $C_{16:0}$ iso (16.2 and 17.3), $C_{15:0}$ iso (10.8 and 11.3), $C_{14:0}$ iso (7.1 and 10.4), 9-methyl-$C_{16:0}$ (9.3 and 7.9), $C_{16:0}$ iso 2-OH (6.5 and 6.3).

Source (type strain): soil from Jeju, Korea.

DNA G+C content (mol%): 68 (T_m).

Type strain: HD9, JCM 12204, KACC 20266, NBRC 101070.

Sequence accession no. (16S rRNA gene): AY253866.

9. **Kribbella karoonensis** Kirby, Le Roes and Meyers, 2006, 1100[VP]

ka.ro.o.nen′sis. N.L. fem. adj. *karoonensis* of or pertaining to the Karoo Desert National Botanical Garden in Worcester, South Africa.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Kirby et al., 2006).

Substrate mycelium is cream/yellow on inorganic salts starch agar (ISP 4) and fragment into rod-shaped elements in broth and on agar media (Figure 273). Aerial mycelium is pale cream/white and fragments into rod-shaped elements. Grows at 20°C (minimal temperature tested) and 37°C, but not at 45°C. Grows well on ISP 2 medium supplemented with 2% NaCl, with weak growth in the presence of 3 or 4% NaCl. Survives in a soil sample heated (dry heating) at 120°C for 1 h. Grows in the presence of (µg/ml) carbenicillin disodium salt (100), chloramphenicol (20), cycloheximide (10), erythromycin (10), and streptomycin sulfate (10). Growth is inhibited by ampicillin sodium salt (100), cefotaxime (10), cephaloridine (10), chloramphenicol (50), gentamycin sulfate (10), neomycin sulfate (10), tobramycin sulfate (10), and vancomycin hydrochloride (10).

Source (type strain): soil collected from the base of a giant quiver tree, *Aloe pillansii*, in the Karoo Desert National Botanical Garden, Worcester, Western Cape Province, South Africa.

DNA G+C content (mol%): not determined.

Type strain: Q41, DSM 17344, JCM 14304, NBRC 101884, NRRL B-24425.

Sequence accession no. (16S rRNA gene): AY995146.

10. **Kribbella koreensis** (Lee, Kang and Hah 2000) Sohn, Ohn, Hong, Bae and Chun 2003, 1007[VP] (*Hongia koreensis* Lee, Kang and Hah, 2000, 197)

ko.re.en′sis. N.L. fem. adj. *koreensis* of or pertaining to Korea, the location of the soil sample from which the type strain was isolated.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the papers of Lee et al. (2000) and Sohn et al. (2003), unless indicated.

Substrate mycelium is usually cream on the media tested and consists of irregularly branched hyphae tending to form apical swellings (observed, e.g. on ISP 3 medium). The hyphae fragment into elongated or short rod-shaped elements; bud-like cells are formed on some media, for instance, on ISP 3 medium (Figure 274). Aerial mycelium is white and fragmenting (Figure 272). Melanin is produced on ISP 7 medium. Grows at 10 and 30°C; growth at 37°C varies with experiments (Kirby et al., 2006; Lee et al., 2000; Trujillo et al., 2006). Grows well on ISP 2 medium in the presence of 2% NaCl (Kirby et al., 2006); no growth occurs at 3% NaCl (Kirby et al., 2006; Lee et al., 2000; Trujillo et al., 2006). Growth is observable at initial pH 7–10. Grows on D-arabinose, D-lyxose, methyl-α-D-glucoside, methyl-α-D-mannoside, and salicin as sole carbon sources; no growth is observed with dextran, D-glucosamine, L-sorbose, and dulcitol. Growth occurs on a tap-water agar (supplemented with cycloheximide and nystatin). Produces pyrrolidonyl arylamidase (API ZYM; Trujillo et al., 2006). Positive response in the API 20NE and ID 32GN systems for utilization of acetate, adipate, L-fucose, gluconate, 3-hydroxybutyrate, itaconate, malate, D-ribose, and suberate as sole carbon sources, and production of β-glucosidase; negative for utilization of caprate, citrate, glycogen, 3- and 4-hydroxybenzoate, 2- and 5-ketogluconate, L-alanine, malonate, phenyl acetate, L-proline, propionate, valerate, L-histidine, and L-serine, as well as reduction of nitrate to nitrogen, production of arginine dihydrolase and indole, and acidification of glucose (Cui et al., 2010). Acid is produced from D-raffinose in the Bacto OF basal medium (Difco); no acid production was found with all other compounds tested: D-glucose, D-arabinose, L-arabinose, D-cellobiose, D-fructose, D-galactose, inulin, D-lactose, maltose, D-mannose, D-melezitose, melibiose, methyl-α-D-glucoside, methyl-α-D-mannoside, L-rhamnose, L-ribose, salicin, sucrose, D-trehalose, D-xylose, adonitol, 2, 3-butanediol, *meso*-erythritol, glycerol, *meso*-inositol, D-mannitol, or 1, 2-propanediol. Gives an alkaline reaction in the tests for utilization of organic acids, such as α-ketoglutarate, malonate, propionate, pyruvate, and *trans*-aconitate with phenol red indicator; negative responses with *cis*-aconitate, benzoate, formate, maleate, salicylate, sebacate, sorbate, or tartarate (according to the method of Gordon et al. (1974). DNA and pectin are not hydrolyzed. Sodium hippurate is decomposed. Resistant to lysozyme, 0.1% (w/v) phenol, 0.01% (w/v) potassium tellurite, 0.00005% (w/v) crystal violet, and 0.001% (w/v) brilliant green, but not to 0.01% (w/v) sodium azide, 0.3% (w/v) phenylethanol, or 0.01% (w/v) thallous acetate. Grows in the presence of (µg/ml) carbenicillin disodium salt (100), cephaloridine (10), chloramphenicol (20, weak), cycloheximide (10), erythromycin (10), neomycin sulfate (10, weak), streptomycin sulfate (10), and vancomycin hydrochloride (10); growth is inhibited by (µg/ml) ampicillin sodium salt (100), cefotaxime (10), chloramphenicol (50), gentamycin sulfate (10), and tobramycin sulfate (10) (Kirby et al., 2006). No antimicrobial activity was observed against *Bacillus subtilis*, *Micrococcus luteus*, *Staphylococcus aureus*, *Streptomyces murinus*, *Escherichia coli*, *Enterobacter aerogenes*, *Saccharomyces cerevisiae*, *Candida albicans*, and *Aspergillus niger*. Produces neuropilin/growth factor complexes (Alitalo et al., 2003). The major

cellular fatty acids (representing >5% of the total recorded in at least one experiment) reported for cultures grown under different conditions were: $C_{15:0}$ anteiso (24.7–36.4), $C_{16:0}$ iso (8.4–24.0), $C_{15:0}$ iso (12.3–20.1), $C_{17:0}$ iso (4.5–9.0), $C_{17:0}$ anteiso (3.1–5.0), 9-methyl-$C_{16:0}$ (<1–12.7), $C_{17:1}$ ω9*c* (<1–5.0), $C_{14:0}$ iso (2.0–5.9), $C_{16:0}$ (<1–6.6), and 10-methy-$C_{16:0}$ (<1–5.1) (Lee et al., 2000; Sohn et al., 2003; Song et al., 2004).

Source (type strain): a gold-mine cave in Kongju, Republic of Korea.

DNA G+C content (mol%): 71.3 (T_m).

Type strain: LM 161, IMSNU 50530, JCM 10977, NBRC 101069.

Sequence accession no. (16S rRNA gene): Y09159.

11. **Kribbella lupini** Trujillo, Kroppenstedt, Schumann and Martinez-Molina 2006, 410[VP]

lu.pi′ni. L. gen. n. *lupini* of lupin, isolated from *Lupinus angustifolius.*

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Trujillo et al., 2006) unless indicated.

Substrate mycelium is white to cream, extensively branching and fragmenting into rod-shaped and coccoid elements. Abundant white aerial mycelia are produced that break up into rod-shaped fragments. Grows at 12 and 37°C. Tolerates up to 7% NaCl, as tested on nutrient agar. Growth is observed at pH 6–9, but not at pH 5 (initial pH values of nutrient agar). Grows on L-sorbose, adipate, gluconate, L-alanine, L-arginine, L-histidine, L-lysine, L-proline, and DL-valine but not caprate and L-serine as sole carbon sources. Acid is produced from glucose. Produces arginine dihydrolase, esterase lipase (C8), acid and alkaline phosphatases, leucine arylamidase, valine arylamidase, α-chymotrypsin, trypsin, α-galactosidase, α-glucosidase, β-glucosidase, *N*-acetyl-β-glucosaminidase, and α-mannosidase but not β-glucuronidase or pyrrolidonyl arylamidase (API ZYM). Sensitive (μg per disk) to amoxicillin (30), gentamycin (10), neomycin (5), novobiocin (5), oxytetracycline (30), streptomycin (300), tobramycin (10), vancomycin (30), and tetracycline (30). Resistant to ampicillin (2 μg/disk), penicillin G (10 U/disk), and rifampicin (2 μg/disk). The purified cell wall contains galactose and an unidentified sugar which is neither arabinose, glucose, mannose, rhamnose, ribose nor xylose. The major fatty acids (>5% of the total), as determined for cells grown in tryptic soy broth, were $C_{15:0}$ anteiso (28.2), $C_{16:0}$ iso (21.3), $C_{17:1}$ iso (11.0), $C_{14:0}$ iso (9.1), $C_{15:0}$ iso (5.3), $C_{16:1}$ iso (8.1), and $C_{17:0}$ anteiso (5.4).

Source (type strain): root nodules of *Lupinus angustifolius.*

DNA G+C content (mol%): 68 (T_m).

Type strain: LU14, DSM 16683, JCM 14303, LMG 22957, NBRC 101883.

Sequence accession no. (16S rRNA gene): AJ811962.

12. **Kribbella sancticallisti** Urzì, De Leo and Schumann 2008, 2095[VP]

sanc.ti.cal.li′sti. L. n. *Sanctus Callistus* Saint Callistus; N.L. gen. n. *sancticallisti* of Saint Callistus, isolated from the Saint Callistus Roman catacombs.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Urzì et al., 2008).

Substrate hyphae (diameter, 0.51 μm) are cream on Luedemann medium (Luedemann, 1968), branched, and tend to penetrate into the agar. Colonies are irregular (diameter 5–10 mm), with lobate margin, crateriform profile, and rough surface that is covered with white aerial hyphae. Produces melanin (weakly) on ISP 7 medium. No distinct formation of rod-shaped elements due to fragmentation has been observed in cultures on Luedemann medium, but morphological structures resembling short chains of non-separated or separated arthrospores are observable by electron microscopy. Grows at 15 and 37°C with weak growth at 10°C. Grows in the presence of 4% NaCl and weakly in the presence of 5% on Luedeman agar (Luedemann, 1968) without $CaCO_3$ addition. Growth occurs at pH 5 and 10 (initial pH values of the above medium). Utilizes gluconate; hydrolyzes DNA and Tweens 20, 40, and 60. Resistant to the following antibiotics (μg/ml) cephaloridine (10), gentamycin sulfate (3), oleandomycin (15), rifampicin (4) tobramycin (1.5), and penicillin G (10 U /ml); growth is inhibited by chloramphenicol (50), streptomycin sulfate (l0), and vancomycin chloride (10). Sensitive to 0.01% lysozyme. The major fatty acids (>10% of the total) determined for three strains grown on TSA at 28°C for 24 h were $C_{16:0}$ iso (24.0–27.6), $C_{15:0}$ anteiso (19.7–20.8), and $C_{15:0}$ iso (9.1–10.8).

Source: deteriorated tufacean surfaces with grey-whitish alterations in the Roman catacombs of St. Callistus (Rome, Italy).

DNA G+C content (mol%): not determined.

Type strain: BC633, DSM 19602, JCM 14969.

Sequence accession no. (16S rRNA gene): AM778577.

13. **Kribbella sandramycini** Park, Yoon, Shin, Suzuki, Kudo, Seino, Kim, Lee and Lee 1999, 750[VP]

san.dra.my.ci′ni. N.L. n. *sandramycinum* sandramycin (an antibiotic); N.L. gen. n. *sandramycini* of sandramycin, intended to mean producing sandramycin.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Park et al., 1999), unless indicated.

Substrate mycelium consists of extensively branched hyphae which penetrate into agar media; they often fragment into rod- to coccoid-shaped and rod elements. Aerial hyphae appear straight or curved and break up into short to elongated rod-like elements. Colonies are pasty and have lichenous shapes with irregular edges. Gram-stain variable. Grows at 20 and 28–30°C; growth at 37°C varies with experiments (Kirby et al., 2006; Park et al., 1999; Trujillo et al., 2006). Weak growth may occur at 40°C. Grows well on ISP 2 medium in the presence of 2% NaCl, with moderate growth at 3% NaCl and weak growth in the presence of 4% NaCl (Kirby et al., 2006). Produces pyrrolidonyl arylamidase (Trujillo et al., 2006). Growth is observed at initial pH 5 and pH 9 (Kirby et al., 2006; Park et al., 1999; Trujillo et al., 2006). Grows in the presence of (μg/ml) carbenicillin disodium salt (100), chloramphenicol (50), cycloheximide (10), erythromycin (10), neomycin sulfate (10), streptomycin

sulfate (10), and vancomycin hydrochloride (10) but not in the presence of (µg/ml) cefotaxime (10), cephaloridine (10), gentamycin sulfate (10), and tobramycin sulfate (10) (Kirby et al., 2006). Produces an anti-tumor antibiotic, sandramycin (Matson et al., 1993). The major fatty acids (>5% of the total at least in one experiment) reported for cultures grown under different conditions were $C_{15:0}$ anteiso (32.2–42.6), $C_{14:0}$ iso (3.0–14.8), $C_{15:0}$ iso (11.2–15.0), $C_{16:0}$ iso (5.6–8.1), $C_{17:0}$ iso (1.6–6.0), $C_{17:1}$ iso ω8*c* (<1–7.5), $C_{17:1}$ ω8*c* (3.9–6.1), and 9-methyl-$C_{16:0}$ (<1–7.0) (Park et al., 1999; Sohn et al., 2003; Song et al., 2004; Trujillo et al., 2006).

Source (type strain): soil in Mexico.

DNA G+C content (mol%): 68.3 (HPLC).

Type strain: ATCC 39419, KCTC 9609, JCM 10340, NBRC 100341.

Sequence accession no. (16S rRNA gene): AF005020, AY253864.

14. **Kribbella solani** Song, Kim, Hong, Cho, Sohn, Chun and Sun 2004, 1347[VP]

so.la′ni. N.L. gen. n. *solani* of *Solanum*, the genus of the potato, *Solanum tuberosum*, from which the type strain was isolated.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Song et al., 2004), unless indicated. The species description is based on the type strain only.

Substrate mycelium is usually cream, the hyphae are broadly branched. Aerial mycelium is white and consists of hyphae fragmenting into rod-shaped elements. Colonies are typically sand-pasty, with irregular edges, and have lichenous shapes. Among the strains tested, the best (but moderate) anaerobic growth of the type strain of this species is observed on ATCC Medium No. 172 (Kirby et al., 2006). According to Urzì et al. (2008), the strain also grows anaerobically on VL agar (Tiecco, 1975). Grows well in liquid organic medium 79 (Prauser and Falta, 1968) and on ISP 2 agar supplemented with 4% NaCl under aerobic conditions; moderate or weak growth is observed in the presence of 5% NaCl on ISP 2 medium, with no growth at 6% (Carlsohn et al., 2007; Everest and Meyers, 2008; Kirby et al., 2006). No growth is observed at initial pH 5 or pH 9 as assessed in liquid organic medium 79 (Carlsohn et al., 2007) and on Bennett's agar (Kirby et al., 2006). Grows on L-histidine, DL-arginine, and nitrate as nitrogen sources. Gives also clear growth on DL-α-amino-*n*-butyric acid, L-4-hydroxyproline, L-valine, L-methionine, and L-phenylalanine as sole nitrogen sources, in contrast to the phylogenetically closest relative *Kribbella hippodromi*, which shows weak or doubtful growth on these amino acids (Everest and Meyers, 2008; Song et al., 2004). Utilizes salicin as a sole carbon source. Produces (weakly) trypsin (Carlsohn et al., 2007). DNA and tributyrin are hydrolyzed but guanine, allantoin, and chitin are not. Tolerant to 0.01% lysozyme, 0.1% phenyl ethanol, and 0.01% potassium tellurite but not to 0.01% sodium azide, 0.01% thallous acetate, and 0.1% phenol. Grows in the presence (µg/ml) of carbenicillin disodium salt (100), chloramphenicol (50), cycloheximide (10), erythromycin (10), neomycin (80), streptomycin (20), tetracycline (4), rifampicin (4), tobramycin sulfate (10, weak), and vancomycin hydrochloride (10), with weak growth in the presence of penicillin G (10 IU/ml); growth is inhibited (µg/ml) by ampicillin sodium salt (100), cefotaxime (10), cephaloridine (10), and treoleandomycin (10) (Kirby et al., 2006; Song et al., 2004). Resists ampicillin (10 µg per disk) and shows weak growth in the presence of imipenem (10 µg per disk) (Carlsohn et al., 2007). No antimicrobial activity against *Bacillus subtilis*, *Micrococcus luteus*, *Streptomyces scabiei*, *Pseudomonas aeruginosa*, *Candida albicans*, *Aspergillus niger*, *Trichoderma harzianum*, *Fusarium acuminatum*, and *Colletotrichum gloeosporioides*. The major fatty acids (>5%) as determined for cultures grown on TSA agar (BBL) (Song et al., 2004) and in tryptic soy broth (Carlsohn et al., 2007) were $C_{15:0}$ anteiso (21.6 and 31.2), $C_{16:0}$ iso (19.5 and 16.9), $C_{15:0}$ iso (5.8 and 10.0), $C_{14:0}$ iso (12.6 and 10.4), and $C_{16:1}$ iso (6.2 and 1.5).

Source (type strain): a potato tuber with scab lesions, Jeju, Korea.

DNA G+C content (mol%): 69 (T_m).

Type strain: DSA1, JCM 12205, KACC 20196, NBRC 101071.

Sequence accession no. (16S rRNA gene): AY253862.

15. **Kribbella swartbergensis** Kirby, Le Roes and Meyers 2006, 1100[VP]

swart.berg.en′sis. N.L. fem. adj. *swartbergensis* of or pertaining to the Groot Swartberg mountain range, South Africa.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Kirby et al., 2006), unless indicated.

Substrate hyphae are cream-colored on inorganic salts/starch agar (ISP 4 medium) and fragment into rod-shaped elements in broth and on agar media. Aerial hyphae appear straight (Figure 271) and white in color on ISP 4 agar. Optimal temperature for growth is 30°C; grows occurs at 20 and 45°C (minimal and maximal temperatures tested). The ability to grow at 45°C readily distinguishes this species from all other kribbellae. It also grows in the presence of 3% NaCl, with weak growth at 4% NaCl as tested on ISP 2 medium. Grows at initial pH 5 (weak) and pH 9 both on Bennett's agar (Kirby et al., 2006) and in liquid organic medium 79 (Carlsohn et al., 2007). Produces trypsin (Carlsohn et al., 2007). Grows in the presence (µg/ml) of carbenicillin disodium salt (100), cephaloridine (10), chloramphenicol (20), cycloheximide (10), erythromycin (10), gentamycin sulfate (10), neomycin sulfate (10, weak), and streptomycin sulfate (10) but not in the presence of ampicillin sodium salt (100), cefotaxime (10), chloramphenicol (50), tobramycin sulfate (10), and vancomycin hydrochloride (10). Carlsohn et al. (2007) reported that the type strain of this species resisted ampicillin (10 µg per disk) and imipenem (10 µg per disk). The major fatty acids (>5%) determined for the culture grown in TSB were $C_{16:0}$ iso (27.4), $C_{15:0}$ anteiso (16.4), 9-methyl $C_{16:0}$ (13.8), $C_{17:0}$ anteiso (11.7), and $C_{15:0}$ iso (5.7) (Carlsohn et al., 2007).

Source (type strain): soil from the banks of the River Gamka, Die Hel, Groot Swartberg mountain range, Western Cape Province, South Africa.

DNA G+C content (mol%): not determined.

Type strain: HMC25, DSM 17345, JCM 14305, NBRC 101885, NRRL B-24426.

Sequence accession no. (16S rRNA gene): AY995147.

16. **Kribbella yunnanensis** Li, Wang, Zhang, Xu and Jiang, 2006a, 1459[VP] (Effective publication: Li, Wang, Zhang, Xu and Jiang 2006b, 33.)

yun.nan.en′sis. N.L. fem. adj. *yunnanensis* of or pertaining to Yunnan, a province of south-west China in which the sample was collected.

Characteristics are as described for the genus and listed in Table 225 and Table 226. Additional information given below is taken from the original paper (Li et al., 2006) unless indicated.

Substrate mycelium is moderate yellow/soft yellow on ISP 2, potato agar, and nutrient agar, and pale yellow or yellow white on ISP 3, ISP 4, ISP 5, and Czapek's agar. The hyphae are extensively branched and often fragmenting into irregular rod-shaped elements. Aerial mycelia develop on all media tested, especially on Czapek's agar; it is typically white on ISP 3, ISP 4, and ISP 5 media and potato agar, yellow-white on ISP 2 medium and Czapek's agar, and pale yellow on nutrient agar. Aerial hyphae fragment into short to elongated rod-like elements which can be arranged in short chains and have an arthrospore appearance on some media, e.g. on ISP 2 agar. Melanin is weakly produced on ISP 7 medium (Urzì et al., 2008). The major fatty acids (>5% of the total) determined in cells grown on TSA at 28°C include $C_{15:0}$ anteiso (31.6), $C_{15:0}$ iso (14.8), $C_{16:0}$ iso (10.2), $C_{14:0}$ iso (7.8), $C_{17:1}$ iso ω9*c* (6.7), and $C_{17:0}$ iso (6.5).

Source (type strain): soil in Yunnan Province, the west of China.

DNA G+C content (mol%): 68.6 (T_m).

Type strain: YIM 30006, CCTCC AA 001019, DSM 15499, JCM 14307, NBRC 103562.

Sequence accession no. (16S rRNA gene): AY082061.

Genus V. **Marmoricola** Urzì, Salamone, Schumann and Stackebrandt 2000, 534[VP] emend. Lee and Lee 2010, 2138

Lyudmila I. Evtushenko

Mar.mo.ri′co.la. L. neutr. n. *marmor* marble; L. masc. suff. -*cola* inhabitant of; *Marmoricola* inhabitant of marble.

Spherical cells, mostly about 0.5–1.0 µm in diameter, that occur singly, in pairs, short chains, or small clusters. Nonmotile or motile**.** Endospores are not formed. **Gram-positive** cell-wall type. Non-acid-fast. **Chemo-organotrophic with a respiratory type of metabolism. Catalase-positive, test for oxidase is usually negative.** Grow under aerobic conditions on a range of standard nutrient media, including the chemically defined (synthetic) media, forming circular, pasty, and **yellow or orange colonies.** Acids are produced oxidatively rather weakly from carbohydrates. Nitrate reduction varies among species. **Mesophilic**, grow best at 28–30°C; no growth occurs at 42°C. Prefer a neutral to mildly alkaline pH; some species are alkalitolerant or display alkaliphilic properties. Usually non-halophilic. **The cell-wall peptidoglycan contains LL-diaminopimelic acid and glycine** as the diagnostic amino acid **(the peptidoglycan type A3γ).** The acyl type of muramic acid is acetyl. **Menaquinones are the only respiratory quinones; the major component is the tetrahydrogenated menaquinone with eight isoprene units, MK-8(H_4).** The cellular fatty acid pattern is dominated by **straight-chain saturated and unsaturated ($C_{16:0}$ and $C_{18:1}$) components. Tuberculostearic ($C_{18:0}$ 10-methyl) acid is usually detected.** Mycolic acids are absent. The principal identified polar lipids are **phosphatidylinositol, phosphatidylglycerol, and diphosphatidylglycerol; phosphatidylcholine may be present.** Occur in various terrestrial and marine environments and can be found in bacterial communities associated with plants and humans.

DNA G+C content (mol%): 72–73 (HPLC).

Type species: **Marmoricola aurantiacus** Urzì, Salamone, Schumann and Stackebrandt 2000, 534[VP].

Further descriptive information

The genus *Marmoricola* belongs to the family *Nocardioidaceae*, order *Propionibacteriales* (formerly suborder *Propionibacterineae* Stackebrandt et al. 1997), and currently harbors five species, with *Marmoricola aurantiacus* as the type species (Table 227). Based on the 16S rRNA gene analysis, the *Marmoricola* species together with *Nocardioides jensenii* and a few related species of this genus form a group at the periphery of the genus *Nocardioides* radiation (Figure 247). The 16S rRNA gene sequence similarities between the recognized *Marmoricola* species range from 95.3 to 98.7%.

The information given below originates from the papers on the descriptions of the genus *Marmoricola* (Urzì et al., 2000) and the species currently assigned to the genus (Dastager et al., 2008b; Lee and Lee, 2010; Lee, 2007a; Lee et al., 2010; Urzì et al., 2000), unless indicated.

Cells of most species are non-motile cocci, ranging from 0.5 to 1.0 µm in diameter (Figure 276) or a bit more, while the coccoid cells of *Marmoricola bigeumensis* are motile and smaller (~0.3–0.5 µm). A rod–coccus morphogenetic cycle does not occur (data for *Marmoricola aurantiacus* and *Marmoricola aequoreus*). Colonies are typically circular, entire, convex, shiny, pasty, and yellow- or orange-pigmented. They may become rough, crater-shaped, or irregularly shaped in old (1–1.5 months) cultures.

Marmoricola aurantiacus contains the cell-wall peptidoglycan A3γ type *sensu* Schleifer and Kandler (1972), with LL-diaminopimelic acid (LL-A_2pm) at the third position of the peptide chain and a single glycine as an interpeptide bridge. The same diamino acid, LL-A_2pm, has been reported for the remaining

Major menaquinone	MK-8(H_4)	MK-8(H_4)	MK-8(H_4)	MK-8(H_4)	MK-8(H_4)
DNA G+C content (mol%)	72.0	72.4	72.9	71.0	72.0
Source of type strain	Marble statue	Beach sandy sediment	Agricultural soil	Volcanic ash	Volcanic ash

[a]Based on characteristics of type strains; see the text for other descriptive characteristics. Data from Urzì et al. (2000), Lee (2007a), Dastager et al. (2008b), Lee and Lee (2010), and Lee et al. (2010). Abbreviations: LL-A_2pm, LL-2,6-diaminopimelic acid; PI, phosphatidylinositol; PG, phosphatidylglycerol; DPG, diphosphatidylglycerol; PC, phosphatidylcholine; PL, unknown phospholipid(s); MK-8(H_4), a menaquinone with eight isoprenoic units in the side chain, two of which are saturated. Symbols: −, negative; +, positive; w, weak or slow; v, variable between experiments; nd, no data available; see the text for other symbols.

[b]The pigmentation intensity and shade may vary depending on the growth medium and the culture age.

[c]The recorded lower and higher growth temperatures are indicated; the actual growth temperature range can be slightly broader for some species (see the text).

[d]Initial pH values of media.

[e]Data from Lee and Lee (2010) and Lee et al. (2010) obtained using ISP 9 (Shirling and Gottlieb, 1966) as basal medium.

[f]The opposite result has been reported by Dastager et al. (2008b) obtained using different test medium.

[g]Either $C_{16:0}$ or $C_{18:1}$ ω9*c* may represent a larger proportion depending on culture conditions (see the text and original papers for the culture conditions and the methods).

[h]$C_{16:1}$ may be undetectable or comprising <1% of the total fatty acids (Lee and Lee, 2010).

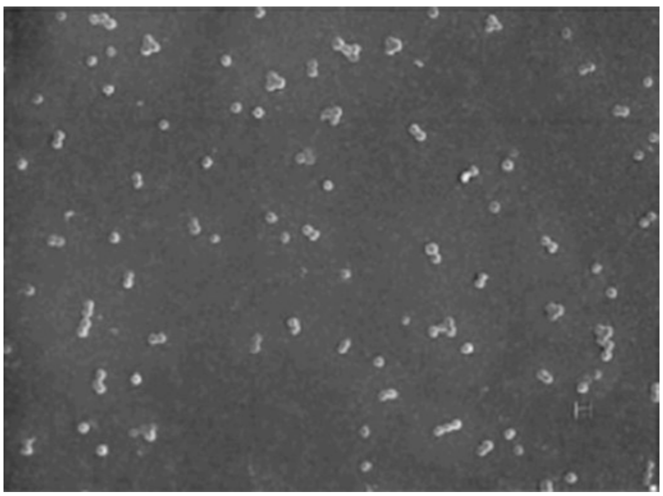

FIGURE 276. Cellular morphology of *Marmoricola aurantiacus*. Cells from a 14-d-old culture on Luedemann medium (Luedemann, 1968). Scanning electron micrograph. Bar = 1 µm. (Reproduced with permission Urzì et al., 2000. Int. J. Syst. Evol. Microbiol. *50*: 529–536.)

species. The acyl type of peptidoglycan is acetyl, as determined for *Marmoricola aurantiacus* (using the glycolate test of Uchida and Aida, 1984). The whole-cell sugars were also reported only for this species and included glucose and traces of ribose. The major component of the respiratory quinone system is MK-8(H_4); minor amounts of MK-7(H_4), MK-8(H_2), and MK-6(H_4) have been reported for *Marmoricola aurantiacus* (peak area ratio, 73:4:1:1). The cellular fatty acids of most species are dominated by straight-chain saturated and straight-chain unsaturated acids. A significant proportion (up to 10%) of tuberculostearic acid ($C_{18:0}$ 10-methyl) can be detected, along with other branched-chain and hydroxylated components occurring in minor or trace amounts (see Table 227 and *List of species of the genus Marmoricola* for more details). In *Marmoricola bigeumensis*, in contrast, branched-chain fatty acids predominate, with $C_{16:0}$ iso comprising 27.6 or almost 60% depending on experiment. All species are characterized by similar principal phospholipids in the polar lipid fraction, including phosphatidylinositol (PI), phosphatidylglycerol (PG), diphosphatidylglycerol (DPG), and an additional unidentified component (unidentified phospholipids in all cases except for *Marmoricola bigeumensis*). There is no evidence, however, that this unidentified component is the same for all species or different. Recently, phosphatidylcholine has been reported in *Marmoricola scoriae* and *Marmoricola korecus* along with PI, PG, DPG, and unidentified phospholipids (Lee and Lee, 2010; Lee et al., 2010).

Bacteria of this genus grow aerobically on a range of standard laboratory media based on peptone and yeast extract, and also display growth on mineral media, e.g. ISP 9* (contains essential salts, trace microelements, and ammonium as a source of nitrogen) supplemented with particular carbon sources, including various carbohydrates, sugar alcohols, organic acids, and other compounds. According to Lee and Lee (2010) and Lee et al. (2010), all species of this genus can grow on ISP 9 with D-glucose, D-mannose, D-mannitol, xylose, or α-methyl-D-glucoside, but not with formate, *meso*-inositol, α-methyl-D-mannoside, or L-sorbose, and display specificity with regard to a variety of other carbon sources (Table 227). Generally, species of this genus are rather non-exacting in their growth requirements, but some may be nutritionally fastidious. *Marmoricola aurantiacus* is unable to grow on certain media rich in organics, including *Corynebacterium* agar (DSMZ medium No. 53). *Marmoricola bigeumensis* has been reported (Dastager et al., 2008b) not to grow on yeast extract-malt extract agar (ISP 2), oatmeal agar (ISP 3), and inorganic salt-starch agar (ISP 4). Bacteria of this genus decompose and hydrolyze a range of

*See Shirling and Gottlieb (1966) for the composition of ISP media cited here and in other sections of this chapter.

*Contains 10 g of glucose, 20 g of soluble starch, 5 g of yeast extract, 5 g of N-Z amine type A, 1 g of $CaCO_3$, 15 g of agar, and 1 liter of distilled water (Cote et al., 1984).

*See Shirling and Gottlieb (1966) for the composition of ISP media cited here and in other sections of this chapter.

complex organic compounds and possess various enzymatic activities (Table 227). In addition, all species show activities for alkaline phosphatase, esterase lipase (C8), leucine arylamidase, α-glucosidase, β-glucosidase, but are negative in tests for lipase (C14), α-galactosidase, β-glucuronidase, *N*-acetyl-β-glucosaminidase, α-mannosidase, and α-fucosidase (the API ZYM assay). All give negative responses in the API 20NE tests for arginine dihydrolase, lysine decarboxylase, ornithine decarboxylase, urease, tryptophan deaminase, and indole production, but are positive in the Voges–Proskauer test. Only two species (*Marmoricola aequoreus* and *Marmoricola bigeumensis*) display positive reaction in the test for nitrate reduction. H_2S production is not observed (examined for *Marmoricola aequoreus* and *Marmoricola scoriae*). All species hydrolyze esculin. Do not decompose carboxymethyl cellulose (data for *Marmoricola korecus* and *Marmoricola scoriae*). *Marmoricola* species so far described are mesophilic and generally considered to be non-halophilic, but some have been reported to grow best at a low salinity (1.5–2% NaCl; *Marmoricola bigeumensis*) or tolerate up to 7% NaCl (*Marmoricola aequoreus* and *Marmoricola bigeumensis*). All prefer a neutral to mildly alkaline pH; some species can grow in test media at high initial pH values (up to pH 12); some exhibit alkaliphilic properties (*Marmoricola scoriae*).

Bacteria of this genus occur in various environments, including nutrient-limited ones. The recognized *Marmoricola* species have been isolated from agricultural soil, sandy beach sediments, volcanic ash, and a marble statue (Table 227). Ecological studies show that representatives of *Marmoricola* or phylogenetically very close organisms occur in soils of different origins, including pastures (Schoenborn et al., 2004) and the mound of a soil-feeding termite (*Cubitermes niokoloensis*; Fall et al., 2007). Bacteria of this genus have also been associated with dust particles transported from desert top soils by Saharan dust storms (Polymenakou et al., 2008) and with urban aerosols (Brodie et al., 2007), and found in indoor environments (Rintala et al., 2008; GenBank no. FM872516 and no. AM697095). They also occur in marine ecosystems (Gontang et al., 2007) and among bacteria cultured from granular activated carbon filters in water treatment installations (Magic-Knezev et al., 2009). Bacteria of the genus *Marmoricola* are detected in human skin microbiome (Grice et al., 2009, 2008; see, e.g. GenBank numbers HM267307, HM326534, etc.) and have been found in microbial populations of bronchoalveolar lavage fluid from children with cystic fibrosis (Harris et al., 2007). A bacterium remotely related to *Marmoricola aurantiacus* was also detected in the rhizosphere-associated bacterial and fungal communities of diseased seedlings (Filion et al., 2004). However, no species or strains pathogenic for humans or warm-blooded animals or plants have yet been identified within the genus *Marmoricola*.

Enrichment and isolation procedures

No selective media or enrichment procedures have been devised for isolating organisms of the genus *Marmoricola*. The available strains of this genus are isolates obtained during studies on microbiota of certain biotopes. *Marmoricola aurantiacus* was isolated from a marble statue on Bunt and Rovira medium (Bunt and Rovira, 1955), modified by the addition of 0.5% glucose, 0.5% NaCl, and 0.03% Na_2CO_3, pH 8.6 (BRII) and further cultivated in Luedemann medium (Luedemann, 1968). *Marmoricola korecus* and *Marmoricola scoriae* were isolated on starch–casein agar (1% soluble starch, 0.03% casein, 0.2% KNO_3, 0.2% NaCl, 0.2% KH_2PO_4, 0.002% $CaCO_3$, 0.005% $MgSO_4 \cdot 7H_2O$, 0.001% $FeSO_4 \cdot 7H_2O$, and 1.8% agar, pH 7.2). SC-SW agar (the same composition but without addition of KH_2PO_4 and prepared in a 60:40 mixture of natural sea water and distilled water; Lee, 2006) was used for isolation of *Marmoricola aequoreus*, and one-tenth-strength R2A agar (Difco) was used for isolation of *Marmoricola bigeumensis*. Isolations were carried out using the serial dilution plating method, followed by incubation at 28–30°C for ~2–4 weeks.

Maintenance procedures

Cultures may be maintained as 20% glycerol suspensions at −20 and −80°C. Long-term conservation is achieved by freeze-drying or in liquid nitrogen by standard procedures.

Differentiation of the genus *Marmoricola* from other genera

The phenotypic characteristics differentiating *Marmoricola* from other genera of the family are listed in Table 214 and Table 216. The genus *Marmoricola* is readily distinguished from most genera of the family by the presence of coccoid cells and predominant menaquinone MK-8(H_4). The same major menaquinone is also characteristic of the genus *Nocardioides*, but members of the latter have mycelial or rod-shaped cell morphologies in young cultures and usually form coccoid cells (along with short rods) at later growth stages. Further, the *Marmoricola* species readily differ from the genus *Nocardioides* in the fatty acid profile dominated by straight-chain compounds (exception is *Marmoricola bigeumensis*). It should be emphasized that delineation of the current genera *Marmoricola* and *Nocardioides*, as a whole, remains somewhat uncertain (See *Taxonomic comments*, below). Therefore, the side-by-side comparison of novel strains with individual species of the genus *Marmoricola* and closely related *Nocardioides* species is advisable during the identification process. Also, (short) rods in some organisms of this group, owing to their possible fast fragmentation into cocci on certain media, may be difficult to observe.

Taxonomic comments

The genus *Marmoricola* was described by Urzì et al. (2000) with one species, *Marmoricola aurantiacus*, represented by a single nonmotile coccoid strain having high (96.4%) 16S rRNA gene sequence similarity with the phylogenetically neighboring species, *Nocardioides jensenii*. The establishment of the genus *Marmoricola* was based on the assumed priority of unusual phenotypic, including chemotaxonomic, features of the strain and its difference from other members of the family *Nocardioidaceae* described by that time in several secondary-structure-forming nucleotides. The key chemotaxonomic marker separating the genus *Marmoricola* from *Nocardioides* included the cellular fatty acid profile (mostly straight-chain components with minor amounts of $C_{18:0}$ 10-methyl). The species *Marmoricola aequoreus*, *Marmoricola scoriae*, and *Marmoricola korecus*, described subsequently (Lee and Lee, 2010; Lee, 2007a; Lee et al., 2010) have generally similar morphological and chemotaxonomic properties to those of *Marmoricola aurantiacus*, except the presence of phosphatidylcholine (detected in *Marmoricola scoriae* and *Marmoricola korecus*). This finding rendered the genus heterogeneous with respect to principal polar lipids, and the genus

description has been emended (Lee and Lee, 2010) to include this characteristic and also reflect some features of *Marmoricola bigeumensis* described in 2008 (Dastager et al., 2008b). The latter was assigned to the genus mainly on the basis 16S rRNA-based phylogenetic clustering (Dastager et al., 2008b).

However, *Marmoricola bigeumensis*, as mentioned before, markedly differs from the other *Marmoricola* species by possessing a large proportion of saturated iso-branched acids and resembling *Nocardioides* by the fatty acid profile. Notably, iso- and anteiso-branched acids are synthesized in a different way than the straight-chain saturated acids (for details and references see Suzuki et al., 1993), and the respective difference in fatty acid composition is typically used as a criterion to differentiate the actinomycete genera (Kroppenstedt, 1985; Suzuki and Komagata, 1983a; Urzì et al., 2000). *Marmoricola bigeumensis* is also distinguished from the other *Marmoricola* species by motile and smaller cells, and exceeds those in NaCl resistance. In addition, it is not quite clear whether the cells of *Marmoricola bigeumensis* are cocci at all growth phases, or arise from (short) rods at later stages of the developmental cycle as in *Nocardioides* species. Furthermore, with the recent descriptions of additional *Marmoricola* species and closely related organisms of the genus *Nocardioides*, it becomes clear that *Marmoricola bigeumensis* is branching outside the group of the remaining *Marmoricola* species. This species is also closest to members of the genus *Nocardioides* (*Nocardioides jensenii* and *Nocardioides mesophilus*) in terms of 16S rRNA gene sequence similarity (97%; calculated from 1420 bp and 1396 bp, respectively), while the sequence similarity to the other *Marmoricola* species is 96.6–95.3% (1398–1435 bp compared). Taken together, all the above data indicate that the current taxonomic structure of the genus *Marmoricola* is in need of re-evaluation to improve coherence of its phylogenetic and phenotypic circumscription and delimitation from the genus *Nocardioides*. The available data suggest that further detailed taxonomic studies of *Marmoricola bigeumensis* at the genomic and phenotypic level, involving available and newly isolated relevant strains, may provide strong grounds for movement of *Marmoricola bigeumensis* to the genus *Nocardioides* or to a new genus.

Differentiation of species of the genus *Marmoricola*

Phenotypic characteristics useful in distinguishing the current *Marmoricola* species are discussed in the above sections and listed in Table 227 and in the *List of species of the genus Marmoricola*, below. When using the compositions of fatty acids and polar lipids for differentiation, note that these characteristics may depend on growth conditions, age of the culture, and analytical procedure. In comparative taxonomic studies, cells must be grown and analyzed under the same conditions.

List of species of the genus *Marmoricola*

1. **Marmoricola aurantiacus** Urzì, Salamone, Schumann and Stackebrandt 2000, 534[VP]

au.ran.ti′a.cus. N.L. masc. adj. *aurantiacus* orange-colored.

Characteristics are as described for the genus and listed in Table 227. Additional information presented below is taken from the original paper (Urzì et al., 2000), unless indicated. Spherical cells (0.5–0.7 µm in diameter) occurring singly, in pairs, as short chains, or small clusters (Figure 276). Nonmotile. No rod–coccus life cycle. Cells are Gram-stain-positive and not lysed in the KOH test. Non-acid-fast. Colonies are orange-pigmented and 2–5 mm diameter after 30-d incubation on Luedemann medium (Luedemann, 1968) at 28°C. Grows at 18°C; no growth occurs at 6 or 37°C. Growth is restricted on Luedemann medium supplemented with 2% NaCl and absent in the presence of 4% NaCl. The type strain will grow on brain heart infusion agar (BHIA; Oxoid), potato glucose agar (PDA; Oxoid), ISP 2 agar, and in Bacto tryptic soy broth (Difco). According to Lee and Lee (2010), growth is also supported by R2A agar (Difco). No growth is observed in several other tested complex media. Will grow on inorganic medium ISP 9 with various carbon sources (Lee and Lee, 2010) but not on Czapek–Dox modified agar (CZ; Oxoid) or on water agar. Acid is not produced from D-glucose, D-ribose, L-arabinose, D-galactose, D-cellobiose, lactose, maltose, D-mannose, D-raffinose, L-rhamnose, D-trehalose, D-xylose, glycerol, D-mannitol, or *myo*-inositol, as registered on the medium containing 0.5% tryptone (Oxoid), 0.4% Bacto Casamino acids (Difco), 0.07% $(NH_4)_2HPO_4$, 0.5% NaCl, 0.003% bromocresol purple, and the substrate at a concentration of 1%. Hydrolyzes Tween 80 (weak). The whole-cell sugars are glucose and traces of ribose. The major cellular fatty acids (about 5% or more at least in one experiment) determined in cells grown in Bacto tryptic soy broth at 28°C (Urzì et al., 2000) and in cells cultured on R2A agar at 30°C for 5 d (Lee and Lee, 2010) are $C_{16:0}$ (41.4 and 37%, respectively), $C_{18:1}/C_{18:1}$ ω9*c* (33.7 and 27), $C_{16:1}/C_{16:1}$ ω9*c* (14.9 and <1), $C_{18:0}$ 10-methyl (2.8 and 5.4), and $C_{16:0}$ 2-OH (1.4 and 4.7). In addition, Lee and Lee (2010) detected a significant amount of $C_{16:1}$ ω7*c* and/or $C_{15:0}$ iso 2-OH (9.9%) in cells from R2A agar.

Source (type strain): a Carrara marble statue (Wagmüller's monument) located in the Nordfriedhof Cemetery in Munich, Germany.

DNA G+C content (mol%): 72.1 (HPLC).

Type strain: BC 361, DSM 12652, CIP 106770, JCM 10917.

Sequence accession no. (16S rRNA gene): Y18629.

2. **Marmoricola aequoreus** Lee 2007a, 1392[VP]

a.e.qu.o.re′us. L. masc. adj. *aequreus* belonging to the sea, referring to the isolation site of the type strain.

Characteristics are as described for the genus and listed in Table 227. Additional information presented below is taken from the papers of Lee (2007a) and Lee and Lee (2010).

Spherical cells (0.5–0.7 μm in diameter) occurring singly, in pairs, as short chains, or small clusters. Nonmotile. No rod–coccus life cycle is observed. Colonies are bright yellow after incubation for 5 d at 30°C on YE-SW agar (ISP 2 agar prepared in a 60:40 mixture of natural sea water and distilled water). Growth is good at 10–37°C (with an optimum at 30°C), poor at 4°C, and absent at 42°C. Will grow on ISP medium 2 with 5% NaCl, but poorly at 6–7% NaCl. Grows at pH 5.1–12.1 (initial pH of medium, YE-SW agar) and optimally at pH 7.1. The type strain produces acid from dextran, maltose, and salicin but not from D-glucose and almost 30 other carbon sources tested using Bacto OF basal medium (Difco) supplemented with a filter-sterilized carbon source at a final concentration of 1%. The cellular fatty acids (>5% at least in one experiment), determined in cells grown on TSA for 3 d at 30°C and on R2A agar for 5 d at the same temperature, include $C_{18:1}$ ω9*c* (40.1 and 26.4), $C_{16:0}$ (35 and 30.2), $C_{18:0}$ (7.6 and 2.3%), $C_{16:1}$ ω9*c* (6.6 and <1). In cells harvested from R2A agar, 10-methyl-branched acids were detected (7.1% $C_{18:0}$ 10-methyl and 1.7% $C_{17:0}$ 10-methyl), as well as $C_{19:0}$ anteiso (6.3%), $C_{16:1}$ 2-OH (4.3%), and $C_{16:1}$ ω7*c* and/or $C_{15:0}$ iso 2-OH (8.2%).

Source (type strain): sandy sediment 1 m below the surface of Samyang Beach on Jeju Island, Republic of Korea.

DNA G+C content (mol%): 72.4 (HPLC).

Type strain: SST-45, JCM 13812, NRRL B-24464.

Sequence accession no. (16S rRNA gene): AM295338.

3. **Marmoricola bigeumensis** Dastager, Lee, Ju, Park and Kim 2008b, 1062[VP]

bi.ge.um.en′sis. N.L. masc. adj. *bigeumensis* of or pertaining to Bigeum Island, Korea, from where the type strain was isolated.

Characteristics are as described for the genus and listed in Table 227. Additional information presented below is taken from the original paper (Dastager et al., 2008b), unless indicated.

Coccoid and motile cells (0.3–0.5 μm in diameter). Colonies are lemon-yellow and 1–3 mm in diameter on R2A agar. Grows in the presence of up to 7% NaCl and at pH 6.0–12.0 (initial pH of medium), but best at 1.5–2% NaCl and pH ~7.2 (all tested on twofold diluted in R2A agar). Will grow in the temperature range of 20–37°C. No growth is observed on yeast extract-malt extract agar (ISP 2), oatmeal agar (ISP 3), and inorganic salt-starch agar (ISP 4). D-Glucose, L-arabinose, L-rhamnose, D-ribose, and D-xylose are utilized as carbon sources for growth and energy, as determined both in the original study (Dastager et al., 2008b) and using ISP 9 as basal medium (Lee and Lee, 2010); growth with D-mannose and D-mannitol is variable (Dastager et al., 2008b; Lee and Lee, 2010). No acid is produced (the Hugh–Leifson test; Hugh and Leifson, 1953) from the aforementioned carbohydrates and also from cellobiose, D-galactose, lactose, maltose, and raffinose. Tween 80 is hydrolyzed. The reported cellular fatty acids [determined in cells grown on Trypticase soy agar plates (BBL) using the procedures described by Miller (1982)] include $C_{16:0}$ iso (59.1%), $C_{17:0}$ anteiso (6.9%), $C_{16:0}$ (4.0%), and $C_{14:0}$ iso (3.3%). A wider spectrum of fatty acids was detected by Lee and Lee (2010) for cells grown on R2A agar at 30°C for 5 d, with $C_{16:0}$ iso predominating (27.6%). The other components (3% or more) were $C_{16:0}$ (6.8), $C_{17:0}$ (3.8), $C_{17:1}$ ω8*c* (6.9), $C_{18:1}$ ω9*c* (4.2), $C_{14:0}$ iso (4.3), $C_{15:0}$ iso (5.5), $C_{17:0}$ iso (3.5), $C_{15:0}$ anteiso (3.3), $C_{17:0}$ anteiso (5.9), $C_{16:0}$ iso 3-OH (3.0), and $C_{16:1}$ 2-OH (3.5); a 10-methyl-branched acid ($C_{17:0}$ 10-methyl) was found as a minor component (2.2%).

Source (type strain): a soil sample collected from an agricultural area of Bigeum Island, Korea.

DNA G+C content (mol%): 72.9 (HPLC).

Type strain: MSL-05, KCTC 19287, JCM 15624, DSM 19426.

Sequence accession no. (16S rRNA gene): EF466120.

4. **Marmoricola korecus** Lee, Lee and Ko 2010, 000[VP]

ko.re′cus. N.L. masc. adj. *korecus* pertaining to Korea, where the type strain was isolated.

Characteristics are as described for the genus and listed in Table 227. Additional information presented below is taken from the original paper (Lee et al., 2010).

Spherical (1.1–1.2 μm diameter) and nonmotile cells. Colonies are yellow-pigmented after incubation for 5 d on ISP 2 agar at 30°C (optimal temperature). Growth occurs at 4–37°C but not at 42°C. Grows on ISP 2 with 2% NaCl (but not with 3%), and in the pH range of pH 5.1–12.1; optimal pH is 6.0–10.1 (initial pH of the same test medium). The major fatty acids determined in cells grown on R2A agar at 30°C for 5 d are $C_{16:0}$, $C_{17:1}$ ω8*c*, $C_{18:1}$ ω9*c*, as well as $C_{16:1}$ ω7*c* and/or $C_{15:0}$ iso 2-OH.

Source (type strain): a red-colored layer of volcanic ash, Jeju, Republic of Korea.

DNA G+C content (mol%): 71.0 (HPLC).

Type strain: Sco-A36, KCTC 19596, DSM 22128.

Sequence accession no. (16S rRNA gene): FN386723.

5. **Marmoricola scoriae** Lee and Lee 2010, 2138[VP]

sco.ri′a.e. L. gen. n. *scoriae* of scoria (volcanic ash), referring to the site from which the type strain was isolated.

Characteristics are as described for the genus and listed in Table 227. Additional information presented below is taken from the original paper (Lee and Lee, 2010).

Spherical cells (0.6–1.0 μm in diameter), occur singly, in pairs or in clusters. Nonmotile. Colonies are vivid yellow, 0.1–0.2 mm in diameter after incubation on ISP 2 agar for 5 d at 30°C (optimal growth temperature). Will grow at 10–37°C but not at 4 or 42°C. Growth occurs at pH 6.1–12.1; optimal pH is 8.1–11.1 (initial pH values of test medium, ISP 2). Grows on the same medium at 1–3% NaCl but better in the absence of NaCl. The major fatty acids (>5% of the total) determined in cells grown on R2A agar at 30°C for 5 d are $C_{16:0}$ (27.7), $C_{18:1}$ ω9 (25.9), $C_{18:0}$ 10-methyl (10.2), $C_{16:0}$ 2-OH (8), as well as $C_{16:1}$ ω7*c* and/or $C_{15:0}$ iso 2-OH (6).

Source (type strain): volcanic ash of Oreum (a parasitic volcanic cone), Jeju, Republic of Korea.

DNA G+C content (mol%): 72.0 (HPLC).

Type strain: Sco-D01, KCTC 19597, DSM 22127.

Sequence accession no. (16S rRNA gene): FN386750.

Order XIII. **Pseudonocardiales** ord. nov.

David P. Labeda and Michael Goodfellow

Pseu.do.no.car.di′a.les. N.L. fem. n. *Pseudonocardia* type genus of the order; suff. *-ales* ending to denote an order; N.L. fem. pl. n. *Pseudonocardiales* the *Pseudonocardia* order.

The order was formed by elevation of the suborder *Pseudonocardineae* Stackebrandt, Rainey, Ward-Rainey 1997, 486[VP] emend. Zhi, Li and Stackebrandt 2009, 599. Labeda et al. (2011) proposed the elimination of the family *Actinosynnemataceae* Labeda and Kroppenstedt 2000 and emended the description of the family *Pseudonocardiaceae* to include the genera formerly found within this family. As a result, the order *Pseudonocardiales* contains a single family and **the description and signature nucleotides of the 16S rRNA gene are that of the family *Pseudonocardiaceae*.**

Type genus: **Pseudonocardia** Henssen 1957, 408[AL].

Family I. **Pseudonocardiaceae** Embley, Smida and Stackebrandt 1989, 205[VP] emend. Labeda, Goodfellow, Chun, Zhi and Li 2010a

David P. Labeda and Michael Goodfellow

Pseu.do.no.car.di.a.ce′a.e. N.L. fem. n. *Pseudonocardia* the type genus of the family; suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Pseudonocardiaceae* the *Pseudonocardia* family.

Aerobic, mesophilic, or thermophilic, Gram-stain-positive, non-acid-fast, catalase-positive, lysozyme resistant, actinomycetes comprising the type genus *Pseudonocardia* (Henssen 1957) emend. Park et al. 2008, as well as the genera *Actinoalloteichus* Tamura et al. 2000, *Actinokineospora* (Hasegawa 1988b) Labeda et al. 2010b, *Actinomycetospora* Jiang et al. 2008, *Actinosynnema* Hasegawa et al. 1978, *Allokutzneria* Labeda and Kroppenstedt 2008, *Amycolatopsis* (Lechevalier et al. 1986) Lee 2009, *Crossiella* Labeda 2001, *Goodfellowiella* Labeda et al. 2008 (previous illegitimate name *Goodfellowia* Labeda and Kroppenstedt 2006), *Kibdelosporangium* Shearer et al. 1986a, *Kutzneria* Stackebrandt et al. 1994, *Lechevalieria* Labeda et al. 2001, *Lentzea* (Yassin et al. 1995) Labeda et al. 2001, *Prauserella* (Kim and Goodfellow 1999) Li et al. 2003a, *Saccharomonospora* Nonomura and Ohara 1971, *Saccharopolyspora* (Lacey and Goodfellow 1975) Korn-Wendisch et al. 1989, *Saccharothrix* (Labeda et al. 1984) Labeda and Lechevalier 1989, *Sciscionella* Tian et al. 2009, *Streptoalloteichus* (Tomita et al. 1987) Tamura et al. 2008b, *Thermocrispum* Korn-Wendisch et al. 1995, and *Umezawaea* Labeda and Kroppenstedt 2007. Figure 277 shows a phylogenetic tree for the genera of the family *Pseudonocardiaceae* calculated from almost-complete 16S rRNA gene sequences.

Morphologically heterogeneous; single or short chains of spores may be present on aerial mycelium and the substrate mycelium. Vegetative mycelium branches, diameter approximately 0.5–0.7 µm; aerial mycelium is produced and fragments into single or chains of smooth-surfaced, rod-shaped elements in some genera. Other structures such as synnemata or dome-like bodies, sporangia or pseudosporangia may be produced by some genera. Some taxa may fail to produce aerial mycelia. Motile spores may be produced by some genera. Marked fragmentation of hyphae occurs in some taxa, but is absent in others. Most taxa are chemo-organotropic, although some are autotrophic. A few taxa are halophilic. Members of the family are found in a diversity of environments, including soils, plant material, manure, and clinical or veterinary samples.

All genera contain *meso*-diaminopimelic acid as the diamino acid in their peptidoglycan and galactose as one of many diagnostic whole-cell sugars. Mycolic acids are not present in any of the genera. Tetrahydrogenated menaquinones of nine isoprene units are characteristic components, although menaquinones containing eight isoprene units predominate in the genus *Pseudonocardia*. The phospholipid profile generally includes phosphatidylethanolamine, sometimes containing hydroxylated fatty acids, as a major constituent, although representatives of one or more genera may also contain phosphatidylcholine. Chemotaxonomic properties of genera of the family are shown in Table 228. The pattern of 16S rRNA signatures consists of nucleotides at positions 127:234 (G–C), 564 (U), 672:734 (U–G), 831:855 (U–G), 832:854 (G–Y), 833:853 (U–G), 952:1229 (U–A), and 986: 1219 (U–A).

DNA G+C content (mol%): 66–76.

Type genus: **Pseudonocardia** Henssen 1957, 408[AL] emend. Park, Park, Lee and Kim 2008, 2477.

Further descriptive information

The family *Pseudonocardiaceae* Embley, Smida and Stackebrandt 1989, 205[VP] emend. Zhi, Li and Stackebrandt 2009, 599 was proposed by Embley et al. (1988a, 1989) and Warwick et al. (1994) on the basis of 16S rRNA gene sequence phylogeny for the genera. The family was emended by Stackebrandt et al. (1997) and, subsequently, Labeda and Kroppenstedt (2000) proposed that the genera *Actinosynnema*, *Actinokineospora*, *Lentzea*, and *Saccharothrix* be placed in the new family *Actinosynnemataceae* based on phylogenetic analysis of 16S rRNA gene sequences for a subset of all taxa within the family. The description of the family *Actinosynnemataceae* was emended by Zhi et al. (2009) to include additional genera described since 2000, namely *Lechevalieria* Labeda et al. 2001 and *Umezawaea* Labeda and Kroppenstedt 2007. A recent study of the taxonomic status of the families *Actinosynnemataceae* and *Pseudonocardiaceae* (Labeda et al., 2010a), based on the 16S rRNA gene sequence data available for the 142 validly named taxa and the chemotaxonomic and morphological properties available from the literature, concluded that the retention of the family *Actinosynnemataceae* could no longer be supported, nor could adequate support be found for any other subdivision of the order *Pseudonocardiales* at this time. It was proposed that the genera within the family *Actinosynnemataceae* be included in the family *Pseudonocardiaceae* and the family description emended accordingly.

Key to the genera of the family *Pseudonocardiaceae*

I. Produces sporangia on the colony surface observable with light microscopy.

A. Polar lipid pattern includes phosphatidylethanolamine containing hydroxylated fatty acids and *lyso*-phosphatidylethanolamine.

→Genus *Allokutzneria*

B. Polar lipid pattern does not include phosphatidylethanolamine containing hydroxylated fatty acids or *lyso*-phosphatidylethanolamine; whole-cell sugar pattern includes arabinose and galactose.

→Genus IX. *Kibdelosporangium*

C. Polar lipid pattern does not include phosphatidylethanolamine containing hydroxylated fatty acids or *lyso*-phosphatidylethanolamine; whole-cell sugar pattern includes galactose and rhamnose.

→Genus X. *Kutzneria*

II. Produces pseudosporangia on the colony surface.

A. Polar lipid pattern includes phosphatidylethanolamine containing hydroxylated fatty acids.

→Genus XVIII. *Thermocrispum*

B. Polar lipid pattern does not include phosphatidylethanolamine containing hydroxylated fatty acids.

1. Polar lipid pattern includes phosphatidylinositol and phosphatidylinositol mannosides; whole-cell sugar pattern includes rhamnose.

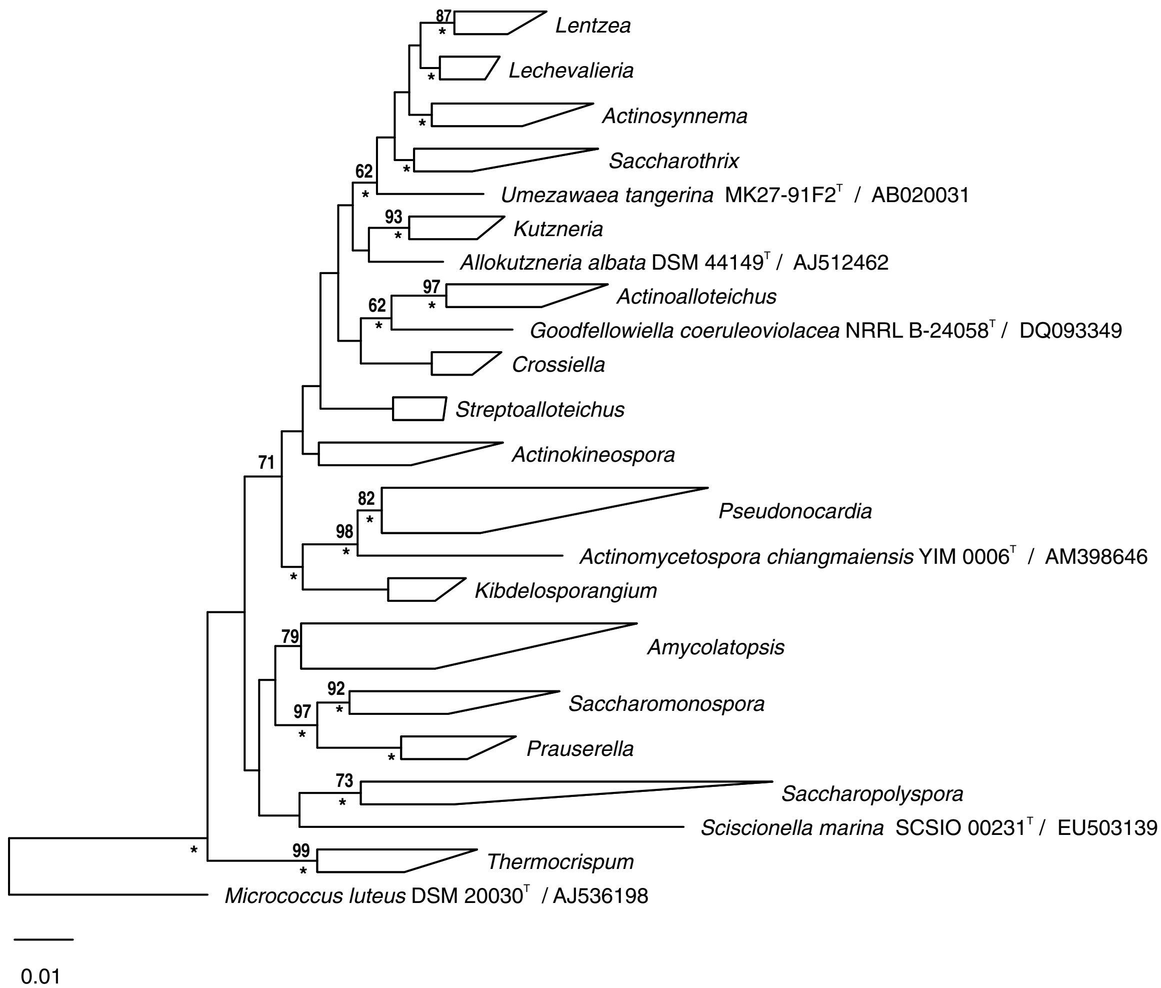

FIGURE 277. Phylogenetic tree for the genera of the family *Pseudonocardiaceae* calculated from almost-complete 16S rRNA gene sequences using the Kimura evolutionary distance method (Kimura, 1980) and the neighbor-joining algorithm of Saitou and Nei (1987). Percentages at the nodes represent levels of bootstrap support from 100 resampled datasets; values less than 60% are not shown. Branches also conserved in maximum-parsimony (Felsenstein, 1993) and maximum-likelihood (Stamatakis et al., 2002) trees are marked with an asterisk. Bar = 0.01 nucleotide substitutions per site.

→Genus VII. *Crossiella*

2. Polar lipid pattern does not include phosphatidylinositol or phosphatidylinositol mannosides; whole-cell sugar pattern does not include rhamnose.

→Genus XVII. *Streptoalloteichus*

III. Does not produce sporangia or pseudosporangia.

A. Produces motile spores.

1. Produces chains of motile spores borne on synnemata or raised dome-like structures on the vegetative mycelium.

→Genus V. *Actinosynnema*

2. Produces chains of motile spores on the aerial mycelia; synnemata not produced

→Genus III. *Actinokineospora*

B. Does not produce motile spores.

1. Does not contain arabinose as a diagnostic whole-cell sugar.

a. Polar lipid pattern includes phosphatidylethanolamine containing hydroxylated fatty acids and *lyso*-phosphatidylethanolamine.

→Genus XIX. *Umezawaea*

b. Polar lipid pattern includes phosphatidylethanolamine containing hydroxylated fatty acids but not *lyso*-phosphatidylethanolamine.

i. Diagnostic whole-cell sugars include mannose and rhamnose.

→Genus XVI. *Saccharothrix*

ii. Diagnostic whole-cell sugars do not include either mannose or rhamnose.

→Genus VIII. *Goodfellowiella*

c. Polar lipid pattern does not include phosphatidylethanolamine containing hydroxylated fatty acids.

i. 16S rRNA gene contains diagnostic nucleotide signature pattern of TT (844–845) and GGT (1107–1109).

→Genus XI. *Lechevalieria*

ii. 16S rRNA gene contains diagnostic nucleotide signature patterns of TCAA (617–620) and GCC (843–845).

→Genus XII. *Lentzea*

2. Contains arabinose as diagnostic whole-cell sugar.

a. Polar lipid pattern contains phosphatidylcholine and/or phosphatidylethanolamine.

[a]Ara, Arabinose; Gal, galactose; Glu, glucose; Mad, madurose; Man, mannose; Rha, rhamnose; Rib, ribose. v, Variable.

[b]DPG, Diphosphatidylglycerol; OH-PE, phosphatidylethanolamine with hydroxy fatty acids; *lyso*-PE, phosphatidylethanolamine where one fatty acid chain is missing from the glycerol backbone; *lyso*-PME, phosphatidylmethylethanolamine where one fatty acid chain is missing from the glycerol backbone; PC, phosphatidylcholine; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PIM, phosphatidylinositol mannosides; PL, unknown phospholipids; PME, phosphatidylmethylethanolamine.

i. Polar lipid pattern includes phosphatidylethanolamine containing hydroxylated fatty acids; predominant menaquinone is MK-8(H_4); chains of spores not produced on aerial mycelia, but vegetative mycelium fragments.
→Genus I. *Pseudonocardia*

ii. Polar lipid pattern does not include phosphatidylethanolamine containing hydroxylated fatty acids; predominant menaquinone is MK-9(H_4); chains of spores not produced on aerial mycelia, but vegetative mycelium fragments.
→Genus *Sciscionella*

b. Polar lipid pattern contains phosphatidylcholine; predominant menaquinone is MK-9(H_4).

i. Short chains of spores, sometimes with spiny to hairy ornamentation, are produced on the aerial mycelia.
→Genus XV. *Saccharopolyspora*

ii. Short chains of smooth-surfaced spores are produced from the vegetative mycelium; phosphatidylinositol and phosphatidylglycerol are only other polar lipids.
→Genus III. *Actinomycetospora*

c. Polar lipid pattern contains phosphatidylethanolamine but not phosphatidylcholine.

i. Single spores, often densely packed, are borne along the aerial mycelium.
→Genus XIV. *Saccharomonospora*

ii. Substrate mycelium fragments into irregular rods; aerial mycelium may be produced which fragments into spore chains; nucleotide signature regions in the 16S rRNA gene sequence include 51 (A/C), 208 (U), 210 (G), 213 (A), 280 (C), 1004 (A), and 1257 (U).
→Genus VI. *Amycolatopsis*

iii. Substrate mycelium fragments into irregular rods; aerial mycelium may be produced which fragments into spore chains; nucleotide signature regions in the 16S rRNA gene sequence include 51 (A), 72 (A), 183:194 (G–C), 208 (G), 210 (A), 213 (C), 280 (U), 1004 (G), and 1257 (G).
→Genus XIII. *Prauserella*

Genus I. **Pseudonocardia** Henssen 1957, 408[AL] emend. Park, Park, Lee and Kim 2008, 2477

Ying Huang and Michael Goodfellow

Pseu.do.no.car′di.a. Gr. adj. *pseudês* false; N.L. fem. n. *Nocardia* a bacterial genus name; N.L. fem. n. *Pseudonocardia* the false *Nocardia*.

Aerobic, Gram-stain-positive, non-acid-fast, nonmotile, catalase-positive, actinomycetes which form branched substrate hyphae that may fragment into rod-shaped elements. Hyphae vary in thickness and in the degree of branching. Aerial hyphae, when formed, may be sterile, fragmented into chains of oval or squarish elements, or into chains of two or more spores. **Substrate and aerial hyphae may exhibit cell division in different directions with a tendency to form apical or intercalary swellings. Spores are usually smooth and are produced on the substrate and/or aerial mycelium by acropetal budding and/or by basipetal septation (fragmentation), or else are formed in longitudinal pairs on vegetative hyphae and singly or in longitudinal pairs on aerial hyphae. In some species, the mycelium is covered by an electron-dense outer layer.** Grows on a variety of organic and synthetic media. Some species are facultative autotrophs. **Cell wall contains *meso*-diaminopimelic acid (*meso*-A2pm), arabinose, and galactose. The major menaquinone is MK-8(H_4) and the predominant fatty acid is iso-branched hexadecanoic acid. Mycolic acids are absent.** The polar lipid profile, which varies between species, may include any of the following: phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylmethylethanolamine, and glucosamine-containing phospholipids. **The 16S rRNA gene sequence contains two unique regions which correspond to nucleotide positions 179–219 and 813–833 of the *Streptomyces ambofaciens* 16S rRNA gene** (Pernodet et al., 1989). The phylogenetic position of *Pseudonocardia*, as determined by 16S rRNA gene sequence analysis, is in the family *Pseudonocardiaceae.*

DNA G+C content (mol%): 68–79 (HPLC, T_m).

Type species: **Pseudonocardia thermophila** Henssen 1957, 408[AL].

Further descriptive information

Phylogeny. The genus *Pseudonocardia* forms a distinct clade in the *Pseudonocardiaceae* 16S rRNA gene tree (Bowen et al., 1989; Embley et al., 1988b, 1988c; Warwick et al., 1994). It encompasses 29 species with validly published names, half of which have been proposed in the past 10 years on the basis of polyphasic taxonomic studies (Chen et al., 2009; Huang et al., 2002; Kämpfer and Kroppenstedt, 2004; Lee et al., 2000a; Park et al., 2008). *Pseudonocardia* species can be phylogenetically assigned to four multimembered clades and one single-membered clade (Figure 278). The earliest described species in the three multi-membered subclades, which are supported by bootstrap values that range from 70 to 100%, are *Pseudonocardia halophobica*, *Pseudonocardia hydrocarbonoxydans*, and *Pseudonocardia nitrificans.* The earliest described species in the least well circumscribed multi-membered subclade is *Pseudonocardia thermophila. Pseudonocardia spinosispora* forms a single-membered clade that is loosely associated with the *Pseudonocardia nitrificans* phyletic line. The most distant phylogenetic relationship in the genus is between the type strains of *Pseudonocardia ammonioxydans* and *Pseudonocardia thermophila* and these organisms share a 16S rRNA gene sequence similarity of 93%. In contrast, the type strains of *Pseudonocardia chloroethenivorans* and *Pseudonocardia dioxanivorans* have identical 16S rRNA gene sequences.

Cell morphology. *Pseudonocardia* strains form extensive substrate and aerial hyphae that vary in the degree of branching and in diameter (0.3–2 µm). Some species, such as *Pseudonocardia asaccharolytica*, *Pseudonocardia halophobica*, and *Pseudonocardia sulfidoxydans*, form swollen hyphal segments up to 5 µm in diameter, zig-zag mycelial growth, and longitudinal and transverse septa in the mycelium (Akimov et al., 1989; Reichert et al., 1998). A characteristic feature of many *Pseudonocardia* species, such as *Pseudonocardia ammonioxydans*, *Pseudonocardia spinosa*, and *Pseudonocardia thermophila*, is acropetal budding (Figure 279, Figure 280, and Figure 281); a constriction is formed behind the tip of the terminal segment, the tip then enlarges to form a new segment, another constriction is formed near the tip, and the process continues (Figure 279, Figure 280, Figure 281, Figure 282, Figure 283, and Figure 284; Henssen and Schäfer,

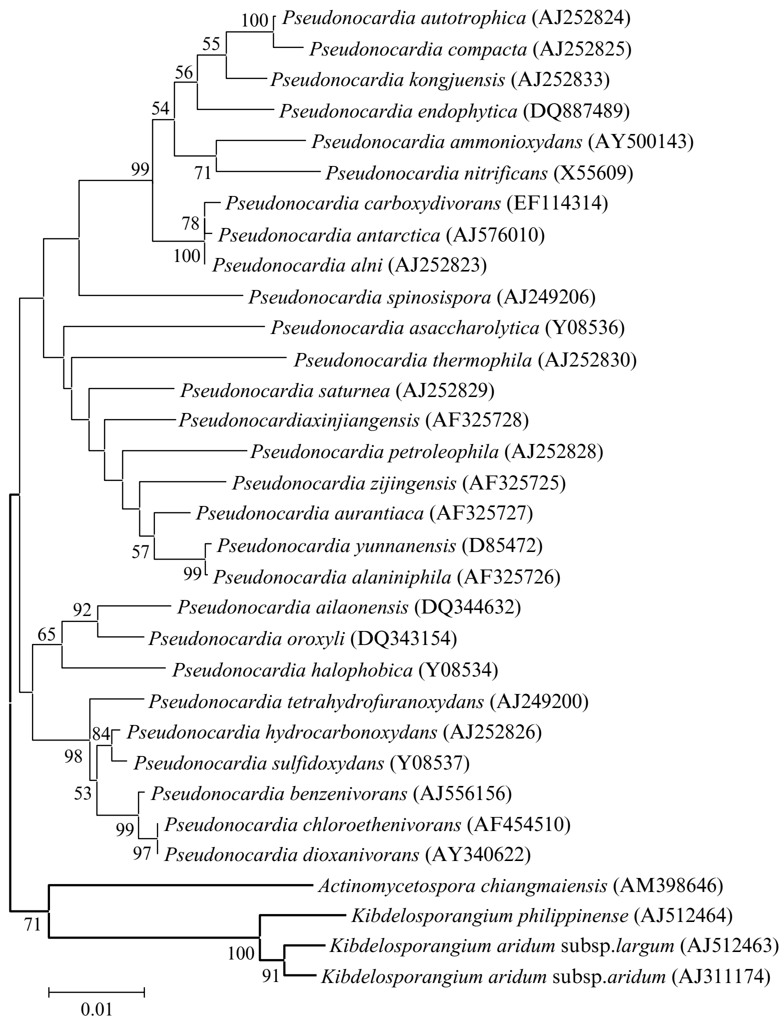

FIGURE 278. Neighbor-joining tree based on nearly complete 16S rRNA gene sequences showing relationships between type strains belonging to the genus *Pseudonocardia*. The numbers at the nodes indicate levels of bootstrap support based on a neighbor-joining analysis of 1000 resampled datasets; only values above 50% are given. Bar = 0.01 substitutions per nucleotide position.

1971). The constrictions may be secondarily separated by septa (Figure 280), which may be formed some distance behind the constriction, as in *Pseudonocardia compacta*. Side branches are usually formed below a septatum, more rarely from the center of a septation (Figure 281 and Figure 282). Aerial hyphae can be sterile, may fragment into chains of squarish to oval fragments, or differentiate into chains of spores (Lechevalier et al., 1986).

Spores may be formed on substrate or aerial hyphae by successive acropetal budding, by basipetal septation (fragmentation), or by irregular spore formation along senescing hyphae (Henssen, 1989; Henssen and Schnepf, 1967). *Pseudonocardia alaniniphila*, *Pseudonocardia aurantiaca*, *Pseudonocardia xinjiangensis*, and *Pseudonocardia yunnanensis* bear spores either in longitudinal pairs on substrate hyphae or singly on aerial hyphae (Xu et al., 1999). In *Pseudonocardia chloroethenivorans*, the aerial and substrate hyphae carry single spores at the ends of hyphae (Lee et al., 2004). Single spores are also formed at the ends of substrate hyphae in *Pseudonocardia tetrahydrofuranoxydans* (Kämpfer et al., 2006). Spores are smooth-walled or spiny and vary greatly in size, but are usually 0.5–1 µm wide by 1.5–4.5 µm long. Spore walls are of uniform thickness and intersporal pads are not formed. In *Pseudonocardia spinosa*, the ornamentation of the spiny spores is formed by folds in the fibrous sheath.

The fine structure of some *Pseudonocardia* species, notably *Pseudonocardia autotrophica*, *Pseudonocardia spinosa*, and *Pseudonocardia thermophila*, has been investigated extensively by Henssen and coworkers (Henssen and Schäfer, 1971; Henssen et al., 1983; Kothe et al., 1989; Kuimova and Malishkaite, 1984). The substrate and aerial mycelial wall of these organisms is composed of two layers: an inner electron-transparent, uniformly thick layer; and an outer electron-dense irregular layer to which the fibrous sheath is attached (Figure 281, Figure 282, and Figure 283). The cross walls are interspace septa (Henssen et al., 1981, 1983) of type 2 *sensu* Williams et al. (1973). Hyphal fragments may become subdivided by septa growing inwards at different angles. Spores of *Pseudonocardia thermophila* show resistance to dry and wet heat at 100°C (Fergus, 1967).

Colony morphology. *Pseudonocardia* strains form well developed colonies on most standard media used to cultivate filamentous actinomycetes (Shirling and Gottlieb, 1966). The substrate

FIGURE 279. Budding, zig-zag-shaped hyphae of *Pseudonocardia spinosa* strain MB SF-1 (light microscopy; bar = 5 µm). (Reproduced with permission from Henssen and Schäfer, 1971. Int. J. Syst. Bacteriol. *21*: 29–34.)

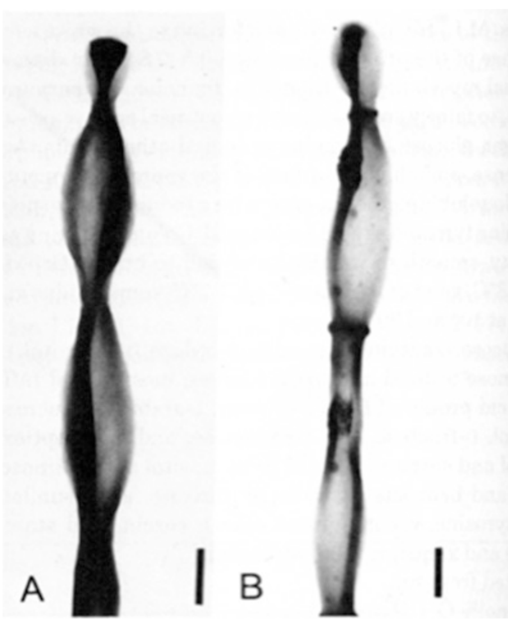

FIGURE 280. A and B. Budding aerial hyphae of *Pseudonocardia thermophila* strain MB-A18.B. Bacteriol. *21*: 29–34.)

mycelium is typically yellowish to brown and the aerial mycelium, if produced, is whitish. The colors of substrate and aerial mycelia, however, can vary between species and are influenced by the cultivation medium. *Pseudonocardia compacta* strains form

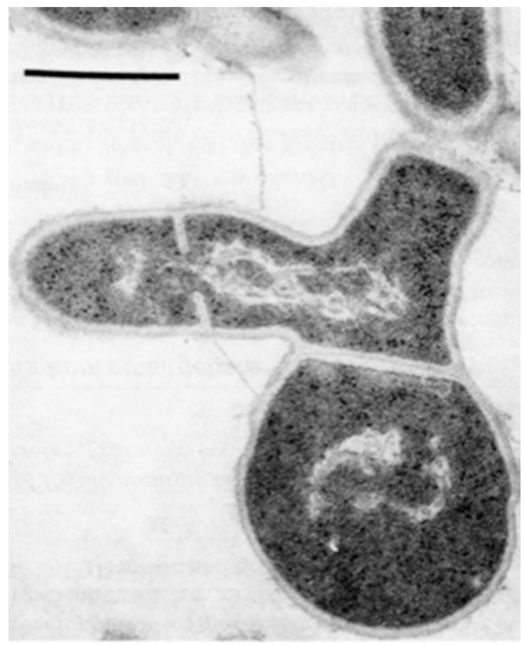

FIGURE 282. *Pseudonocardia thermophila* MB-A18: tip of aerial hyphae with apical swelling and side branch showing septate formation (TEM, glutaraldehyde/osmium tetroxide fixation; bar = 0.5 µm).

lumpy colonies composed of densely aggregated aerial hyphae, which frequently bear apical and intercalary swellings (Henssen et al., 1983). The straight or occasionally helically twisted hyphae of these organisms are more or less regularly segmented. The substrate mycelium of *Pseudonocardia spinosa* forms a compact mass composed of non-septate hyphae of various thicknesses constricted at intervals (Henssen and Schäfer, 1971).

Cell-wall composition. The peptidoglycan of *Pseudonocardia* strains contains *meso*-A_2pm, arabinose, and galactose; these components, which are observed in whole-organism hydrolysates (Embley, 1992; Huang et al., 2002; Reichert et al., 1998; Takeuchi et al., 1992; Warwick et al., 1994), are typical of wall chemotype IV *sensu* Lechevalier and Lechevalier (1970). They typically contain tetrahydrogenated menaquinones with eight isoprene units [MK-8(H_4)] as the predominant isoprenologue

(Chen et al., 2009; Collins et al., 1985; Huang et al., 2002; Kroppenstedt, 1985; Liu et al., 2006; Qin et al., 2008b) and iso-branched hexadecanoic acid ($C_{16:0}$ iso) as the major fatty acid (Gu et al., 2006; Huang et al., 2002; Kroppenstedt, 1985; Park et al., 2008), but lack mycolic acids (Goodfellow and Minnikin, 1981; Lechevalier et al., 1986; Lee et al., 2004). *Pseudonocardia* species may exhibit either a phospholipid type II (phosphatidylethanolamine or its derivatives as major diagnostic components) or type III (phosphatidylcholine) pattern *sensu* Lechevalier et al. (1981, 1977a). Variations in fatty acid profiles and polar lipid patterns are cited in the species descriptions. *Pseudonocardia carboxydivorans* is unusual as it contains MK-9 as the predominant menaquinone (Park et al., 2008).

Nutrition and growth conditions. Many pseudonocardiae grow on standard media, such as Czapek (Waksman, 1967), glucose-asparagine (ISP medium 5, Shirling and Gottlieb, 1966), and yeast extract (Henssen, 1989) agars. Some species such as *Pseudonocardia petroleophila*, however, grow poorly on most media (Hirsch and Engel, 1956). *Pseudonocardia spinosispora* produces sparse, if any, substrate mycelium on most agar media, but does grow in stationary, but not shaken, broth cultures (Lee et al., 2002). *Pseudonocardia halophobica* does not grow in the presence of 3% NaCl (Akimov et al., 1989). Most pseudonocardiae grow well between 15 and 37°C, although *Pseudonocardia thermophila* grows optimally between 40 and 50°C (Henssen, 1957) and *Pseudonocardia antarctica* is psychrotolerant (Prabahar et al., 2004a).

Metabolism. *Pseudonocardia* strains have an oxidative metabolism and exhibit considerable physiological versatility. Some species, such as *Pseudonocardia ammonioxydans*, *Pseudonocardia autotrophica*, *Pseudonocardia dioxanivorans*, *Pseudonocardia petroleophila*, and *Pseudonocardia saturnea*, are facultative autotrophs, whereas most *Pseudonocardia* species are heterotrophs. *Pseudonocardia autotrophica*, *Pseudonocardia petroleophila*, and *Pseudonocardia saturnea* grow in the presence of CO_2, H_2, and O_2 (Hirsch and Engel, 1956; Lechevalier et al., 1986; Takamiya and Tubaki, 1956); *Pseudonocardia carboxydivorans* uses CO as a sole carbon source (Park et al., 2008); *Pseudonocardia ammonioxydans* oxidizes ammonia to nitrate as an energy source, and grows autotrophically on modified nitrifying medium and heterotrophically on Luria–Bertani medium (Liu et al., 2006).

Pseudonocardia (previously *Amycolata*) *autotrophica* strains can degrade lignin and related phenolic compounds (Ball et al., 1989; Haider et al., 1978; Malarczyk et al., 1987; McCarthy and Broda, 1984). When grown in a medium containing carbohydrates and supplemented with a radiolabeled dehydropolymer of coniferyl alcohol they show a wide variety of activities, releasing $^{14}CO_2$ from the methoxyl group, the 2-carbon of the side chain, and from the benzene ring (Haider et al., 1978). In contrast, only small amounts of $^{14}CO_2$ were released from the labeled lignin component of corn stalks and *Pseudonocardia autotrophica* strains also do not significantly degrade ^{14}C-lignin labeled wheat lignocellulose (McCarthy and Broda, 1984). Malarczyk et al. (1987) studied the metabolism of radiolabeled methoxyphenolic acids supplied to *Pseudonocardia autotrophica* strains as sole carbon sources and found that they could release $^{14}CO_2$ from vanillic acid irrespective of the position of the label, and from ring-labeled benzylovanillic, isovanillic and veratric acids. They proposed a pathway for the degradation of vanillic acid that proceeded via guaiacol, isovanillic acid, and protocatechuic acid.

Pseudonocardia hydrocarbonoxydans and *Pseudonocardia petroleophila* grow well in an atmosphere containing simple hydrocarbons (Hirsch and Engel, 1956; Nolof and Hirsch, 1962); *Pseudonocardia hydrocarbonoxydans* is able to partially oxidize gaseous

aldehydes, hydrocarbons, monocarboxylic acids (C_6–C_{14}), and two dicarboxylic acids, namely sebacic and succinic acids (Lacey, 1988; Nolof, 1962). *Pseudonocardia petroleophila* oxidizes the cyclohexane ring of methylcyclohexane (Tonge and Higgins, 1974) and *Pseudonocardia nitrificans* is unusual in its ability to convert ethyl-, ethyl-N-ethyl-, *n*-butyl-, and *n*-propyl-carbamates to nitrite and use these compounds as sole carbon, energy, and nitrogen sources (Isenberg et al., 1954). *Pseudonocardia* sp. strain TY-7 oxidizes propane to 1-propanol and 2-propanol through both terminal and subterminal oxidations (Kotani et al., 2006).

Pseudonocardiae have physiological properties which suggest that they may play a role in the degradation of hazardous compounds and in biogeochemical cycles: *Pseudonocardia asaccharolytica* and *Pseudonocardia sulfidoxydans* utilize dimethyl disulfide as an energy source (Reichert et al., 1998); *Pseudonocardia benzenivorans* utilizes 1,2,3,5-tetrachlorobenzene as a sole carbon source (Kämpfer and Kroppenstedt, 2004); *Pseudonocardia chloroethenivorans* degrades chloroethene, *cis*-1,2-dichloroethene, and trichloroethene, and metabolizes phenol as a source of carbon and energy by a *meta*-cleavage pathway (Lee et al., 2004); *Pseudonocardia dioxanivorans* degrades 1,4-dioxane (Mahendra and Alvarez-Cohen, 2005); and *Pseudonocardia hydrocarbonoxydans* oxidizes hydrocarbons (Lechevalier et al., 1986; Nolof and Hirsch, 1962). Similarly, *Pseudonocardia nitrificans* oxidizes urethane to nitrite as a sole source of carbon, nitrogen, and energy (Schatz et al., 1954). *Pseudonocardia* sp. strain ENV478 degrades 1,4-dioxane and other potentially important ether pollutants and, hence, may be a useful biocatalyst for *in situ* and *ex situ* systems designed for treating recalcitrant pollutants (Vainberg et al., 2006).

Pseudonocardia thermophila exhibits an inducible exo- and intracellular carboxymethylcellulase and β-D-glucosidase activity, although these attributes are suppressed in the presence of free glucose (Malfait et al., 1984). Isolates of *Pseudonocardia thermophila* from cattle compost metabolize different types of native and crystalline cellulose under laboratory conditions (Goddon and Penninckx, 1984). Ca^{2+}-alginate-immobilized cells of *Pseudonocardia thermophila* IFO (now NBRC) 12133 have been used to produce optically active α-hydroxy-esters (Ishihara et al., 1997).

It is evident from the phylogenetic tree calculated from 16S rRNA gene sequences that the type strains of *Pseudonocardia benzenivorans*, *Pseudonocardia hydrocarbonoxydans*, *Pseudonocardia sulfidoxydans*, and *Pseudonocardia tetrahydrofuranoxydans* form a distinct subclade with high bootstrap support (Figure 278). All of these organisms grow on 4-aminobutyrate, 4-hydroxybutyrate, serine, and succinate (each at 10 mM) although the growth yields differ (Kämpfer et al., 2006). Moreover, these species, as well as *Pseudonocardia dioxanivorans*, tolerate a high concentration of tetrahydrofuran (THF, 60 mM), but exhibit differences in their ability to form visible cell aggregations in liquid media containing this compound (Kämpfer et al., 2006; Mahendra and Alvarez-Cohen, 2005). *Pseudonocardia benzenivorans* and *Pseudonocardia sulfidoxydans* form cell aggregates at a low THF concentration (10 mM), whereas *Pseudonocardia hydrocarbonoxydans* and *Pseudonocardia tetrahydrofuranoxydans* exhibit dispersed cell suspensions at this concentration. THF degradation in *Pseudonocardia tetrahydrofuranoxydans* is initiated by a three-component binuclear iron-containing monooxygenase which contains an NADH-dependent reductase component with an unusual covalently bound flavin (Thiemer et al., 2001, 2003).

In general, *Pseudonocardia* species produce acid from a range of sugars and use diverse compounds as sole carbon and nitrogen sources, but tend to vary in their ability to degrade adenine, casein, gelatin, hypoxanthine, starch, tyrosine, and xanthine (Chen et al., 2009; Goodfellow, 1971; Lechevalier et al., 1986; Lee et al., 2004; Liu et al., 2006; Orchard and Goodfellow, 1980; Prabahar et al., 2004a). They are also a potentially rich source of useful enzymes, as exemplified by *Pseudonocardia thermophila*, which produces cobalt-containing nitrile hydratases (Miyanaga et al., 2001; Peplowski et al., 2007) and a constitutively expressed thermostable amidase (Egorova et al., 2004), as well as exhibiting cellulase and xylanase activity (Li et al., 1984; Malfait et al., 1984; Zimmermann et al., 1988). *Pseudonocardia autotrophica* strains can convert vitamin D_3 into hydroxylated active forms, such as 1α and 2α,25-dihydroxyvitamin D_3 (Kim et al., 2002b; Takeda et al., 2006). Kang et al. (2006) optimized the culture conditions for the bioconversion of vitamin D_3 to 1α,25-dihydroxyvitamin D_3 using *Pseudonocardia autotrophica* ID 9302. *Pseudonocardia* strains are also known to metabolize 4-ethylpyridine and 4-methylpyridine (Lee et al., 2006a), and polyethylene glycol (Yamashita et al., 2004).

Pseudonocardia strains have been reported to produce antimicrobial compounds such as the novel glycopeptides helvecardins A and B (Takeuchi et al., 1991), phenazostatin D (Maskey et al., 2003), and eight new quinolone compounds with selective and potent anti-*Helicobacter pylori* activity (Dekker et al., 1998). There has also been a report that *Pseudonocardia autotrophica* produces a broad spectrum antifungal compound (Antoun et al., 1978). *Pseudonocardia* strains isolated from coastal soils have also been found to produce metabolites inhibitory against *Micrococcus luteus* (Srivibool and Sukchotiratana, 2006).

Genetics. There have been relatively few studies on the genetics of *Pseudonocardia* strains, although a nitrile hydratase gene from *Pseudonocardia thermophila* has been cloned and sequenced (Yamaki et al., 1997), as has the gene for cytochrome P-450 hydroxylase in *Pseudonocardia autotrophica* (Kim et al., 2002b). There have been studies on gene clusters involved in fatty acid metabolism in *Pseudonocardia autotrophica* BCRC 12444 (Chen et al., 2005), THF degradation in *Pseudonocardia tetrahydrofuranoxydans* (Thiemer et al., 2003), and on the cloning and expression of a gene that encodes an ether-bond-cleaving enzyme, diglycolic acid dehydrogenase, in polyethylene glycol-utilizing *Pseudonocardia tetrahydrofuranoxydans* $K1^T$ (Yamashita et al., 2004). Two gene clusters encoding putative propane monooxygenases have been cloned from *Pseudonocardia* sp. strain TY-7 and shown to be induced by *n*-alkanes, suggesting that the products of these genes are involved in gaseous *n*-alkane oxidation (Kotani et al., 2006).

A cryptic polyene gene cluster has been isolated and partially characterized from a strain of *Pseudonocardia autotrophica*, an organism that does not exhibit antifungal activity (Lee et al., 2006b), and this strain was shown to contain a novel polyene-specific cytochrome P-450 hydroxylase (CYP) genes. Genomic DNA library screening using the probe for the polyene-specific CYP gene identified a positive cosmid clone containing a DNA fragment of approximately 34.5 kb. Complete sequencing of this DNA fragment showed the presence of seven complete and two incomplete open reading frames that were found to be unique, but comparatively similar to previously known polyene biosynthetic genes. The nine open reading frames were thought to be involved in the biosynthesis of a novel cryptic *Pseudonocardia* polyene metabolite. Polyene-specific CYP genes were not detected, however, in representatives of several other

Pseudonocardia species (Hwang et al., 2007). Two large cryptic plasmids, about 80 and 120 MDa, have also been detected in *Pseudonocardia alni* strains (Dobritsa, 1984).

Pathogenicity. There is no definitive evidence that *Pseudonocardia* strains have a role as clinical or veterinary pathogens. *Pseudonocardia autotrophica* has been occasionally isolated from clinical materials and may be an opportunistic pathogen of immunocompromised hosts (Mishra et al., 1980; Schaal and Beaman, 1984). In addition, unidentified *Pseudonocardia* strains have been associated with allergic diseases in Kuwait (Diab and Al-Gunaim, 1982).

Antibiotic sensitivity. Little is known about the antibiotic sensitivity patterns of *Pseudonocardia* species, although certain closely related species can be distinguished on the basis of their susceptibility to a range of antibiotics (Evtushenko et al., 1989; Prabahar et al., 2004a; Xu et al., 1999). The antibiotic sensitivity profiles of individual taxa, where known, are provided in the species descriptions.

Ecology. Pseudonocardiae have been primarily isolated from enrichment cultures, plant materials, and soils, but have also been recovered from various other habitats, including air, clinical materials, coastal and marine sediments, composts, and sludge, although population numbers, distribution, and roles of *Pseudonocardia* species in natural habitats is virtually unknown. Several species, including *Pseudonocardia ailaonensis*, *Pseudonocardia alaniniphila*, *Pseudonocardia aurantiaca*, *Pseudonocardia xinjiangensis*, *Pseudonocardia yunnanensis*, and *Pseudonocardia zijingensis*, were isolated from soils collected in Yunnan and Xinjiang Provinces in China (Huang et al., 2002; Jiang et al., 1991; Qin et al., 2008b; Xu et al., 1999). Similarly, *Pseudonocardia ammonioxydans* was isolated from a coastal sediment (Liu et al., 2006), *Pseudonocardia antarctica* from a moraine sample from the McMurdo Dry Valleys region of Antarctica (Prabahar et al., 2004a), *Pseudonocardia benzenivorans* from contaminated soil (Kämpfer and Kroppenstedt, 2004), and *Pseudonocardia kongjuensis* and *Pseudonocardia spinosispora* from gold mine cave soil (Lee, 1996; Lee et al., 2001, 2002).

Several (Aragno and Schlegel, 1981)species have been isolated from plant materials, including *Pseudonocardia alni*, which is thought to be associated with the nitrogen-fixing root nodules and rhizospheres of the alder species *Alnus glutinosa* and *Alnus incana* (Evtushenko et al., 1989; Sharaya et al., 1982) where it might utilize the excess hydrogen produced by nitrogen-fixing bacteria (Aragno and Schlegel, 1981). *Pseudonocardia asaccharolytica* and *Pseudonocardia sulfidoxydans* were isolated from bark compost biofilters in an animal rendering plant (Reichert et al., 1998), *Pseudonocardia endophytica* from the Chinese medicinal plant, *Lobelia clavata* (Chen et al., 2009), and *Pseudonocardia oroxyli* from the surface-sterilized elongation root zone of *Oroxylum indicum*, another traditional Chinese medicinal plant (Gu et al., 2006). Enrichment cultures from contaminated industrial sludge and waste water plants led to the isolation of strains of *Pseudonocardia benzenivorans* (Kämpfer and Kroppenstedt, 2004) and *Pseudonocardia tetrahydrofuranoxydans* (Kämpfer et al., 2006), respectively. *Pseudonocardia* strains have been isolated from marine sediments following their detection using culture-independent procedures (Maldonado et al., 2005).

It seems likely that *Pseudonocardia* species with an ability to oxidize hydrogen and fix carbon dioxide (Aragno and Schlegel, 1981; Hirsch, 1960) are widely distributed in hydrogen-rich habitats that are abundant in nature (Aragno and Schlegel, 1981). *Amycolata autotrophica* is able to colonize the surfaces of substrates and actively oxidizes hydrogen when continuously supplied with a mixture of H_2:O_2:CO_2 (7:2:1) in the presence of a small amount of mineral medium (Kriukov, 1981). This organism has been isolated from decomposing vegetable matter, marshland, and soil (Kuznetsov et al., 1978; Lechevalier et al., 1986; Okazaki et al., 1983), and from degraded polyester polyurethane (Pommer and Lorenz, 1986). *Pseudonocardia autotrophica* has been shown to have the capacity to degrade methoxyphenolic compounds (Haider et al., 1978; Malarczyk et al., 1987) and thus may have a role in the turnover of phenolic compounds derived from lignin degradation.

The relative biodiversity of toluene-degrading bacteria isolated from a compost biofilter treating toluene vapor was studied by Juteau et al. (1999). The toluene-degrading community was composed of *Pseudonocardia* and *Rhodococcus* strains that dominated usually faster-growing bacteria, such as members of the genera *Acinetobacter* and *Pseudomonas*. These authors considered that the actinomycetes might be *K*-strategists (adapted to a resource-restricted and crowded environment) and that the compost biofilter was a *K*-environment. These observations would explain why the actinomycetes were not outnumbered by the faster-growing acinetobacters and pseudomonads, which can be considered as *r*-strategists (adapted to a resource-abundant and undercrowded environment).

Pseudonocardia thermophila has been isolated from cattle manure and may play a part in the turnover of plant materials (Goddon and Penninckx, 1984; Henssen, 1989; Malfait et al., 1984). Goddon and Penninckx (1984) studied the succession of the microflora in composting cattle manure using a bench-scale reactor and observed that *Pseudonocardia thermophila* was one of the most abundant actinomycetes [approx. 10^6–10^7 colony forming units (c.f.u.)/g dry weight compost] when the temperature exceeded 40°C, although the numbers stabilized around 10^5–10^6 c.f.u./g after 15 d when the temperature fell to 10°C.

Morón et al. (1999) generated genus-specific primers for PCR identification of *Pseudonocardia* species. The primers were used to identify 106 strains presumptively assigned to the family *Pseudonocardiaceae* that had been isolated from geographically diverse soil and decomposing plant material samples. Nearly half of the isolates produced the genus-specific amplification product and partial 16S rRNA gene sequencing of representative isolates was used to validate their genus assignment. Fatty acid analyses of all of the isolates showed that they formed a heterogeneous group indicating that the genus *Pseudonocardia* is underspeciated.

Mutualistic associations. Attine leaf-cutting ants maintain two highly specialized, vertically transmitted, mutualistic symbionts, basidiomycete fungi (*Agaricales*: mostly *Lepiotaceae*: *Leucocopineae*) that are cultivated for food in underground gardens (Chapela et al., 1994; Martin, 1970; Weber, 1966, 1972), and pseudonocardiae, which produce antibiotics that specifically inhibit the growth of *Escovopsis* parasites (*Ascomycota*: anamorphic *Hypocreales*) of the fungal gardens (Cafaro and Currie, 2005; Currie et al., 1999a, 1999b, 2003a; Kost et al., 2007). The ants provide the fungus with fresh substrate and protection against competition and pathogens (Bass and Cherett, 1994; Mueller et al., 2004 ; North et al., 1997), and virgin ant queens carry their mother's symbiont when leaving their colony to mate. In return, the fungus produces nutrient-rich bodies (gongylidia), which workers harvest as a sole source of food for their larvae and the queen. The relationships between attine ants, their fungal cultivars, pseudonocardial mutualists, and cultivar antagonists is considered to be one that has evolved over 50 million years (Currie, 2001; Currie et al., 2003b, 2006; Mueller et al., 2001; Schultz and Brady, 2008).

The fungal gardens are propagated asexually as clonal monocultures and hence are susceptible to parasitism by micro-organisms that are competitively superior to the fungus cultivated by the ants (Weber, 1966), notably to a highly specialized parasite belonging to the genus *Escovopsis* (Currie et al., 1999a). Genetically diverse strains of the horizontally transmitted pathogen (Gerardo et al., 2006; Taerum et al., 2007) are capable of rapidly devastating fungal gardens and thereby threaten the survival of ant colonies (Currie et al., 1999a; Currie and Stuart, 2001). Bioassay and *in vivo* infection experiments indicate differences in the inhibitory capabilities of ant-associated *Pseudonocardia* strains, as well as variation in *Escovopsis* strain susceptibility to different antibiotics (Poulsen et al., 2007).

Pseudonocardial symbionts typically reside on the cuticle of ants in elaborate cuticular crypts linked to endocrine glands, which apparently produce nutrients to support bacterial growth (Currie et al., 2006). A degree of broad-scale co-evolution is considered to be apparent between *Pseudonocardia* and fungus-growing ants (Cafaro and Currie, 2005), though this relationship is not clear-cut due to the ability of *Pseudonocardia* strains to cross attine species boundaries, both within and between genera (Poulsen et al., 2005). These workers detected frequent *Pseudonocardia* exchanges between sympatric ant species within the genus *Acromyrineae*, thereby indicating that horizontal transmission had occurred. However, symbiotic recognition and behavioral choice may play a crucial role in the fungus-growing, ant-pseudonocardial mutualism (Bot et al., 2001; Mueller et al., 2004; Viana et al., 2001), possibly by recognizing clone-specific chemical signatures (Richard et al., 2007). The operation of such factors might allow ants to retain the ecological flexibility they need to defend their gardens from *Escovopsis* strains and, at the same time, resolve potential conflict that can arise from rearing competing symbiotic *Pseudonocardia* strains (Zhang et al., 2007b).

Symbiotic pairing assay experiments have revealed the presence and extent of antagonistic interactions between *Pseudonocardia* symbionts of fungus-growing ants (Poulsen et al., 2007). The widespread ability of ant-associated pseudonocardiae to inhibit one another suggests that competition will often arise when *Pseudonocardia* strains mix and that such interactions may have a direct impact on host/symbiont dynamics. Indeed, the detection of antagonistic interactions across the phylogenetic diversity of pseudonocardial symbionts indicates that such interactions may have shaped the ant/pseudonocardial symbioses from its inception. Antagonism between *Pseudonocardia* strains can be expected to prevent new strains from gaining a foothold in ant colonies, thereby enforcing single strain rearing within individual ant colonies. However, while ant recognition of *Pseudonocardia* strains may prevent conflict between them, it may also allow ants to replace their resident *Pseudonocardia* strain with an organism that produces novel antibiotics against the garden parasite, *Escovopsis*. The results of the experiments conducted by Poulsen and his colleagues support the view that the evolution of sociality required dramatic increases in anti-microbial defenses and that micro-organisms have been powerful selective agents (Stow and Beattie, 2008).

The coevolution of attine ants and pseudonocardiae has been reassessed by Mueller et al. (2008). They found that phylogenetic data from culture-dependent and -independent microbial surveys indicated close relationships between free-living and ant-associated pseudonocardiae, and a lack of topological correspondence between ant and *Pseudonocardia* phylogenies, indicating frequent pseudonocardial acquisition from environmental sources. Identity of ant-associated pseudonocardiae and isolates from plants and soil implicated them as sources from which attine ants acquire *Pseudonocardia* strains. These data are at variance with the prevailing views of specific coevolution between attine ants, pseudonocardiae, and garden diseases. Consequently, the effectiveness of pseudonocardial antibiotics may not be due to advantages in the coevolutionary arms race with specialized garden diseases, but from the frequent recruitment of effective *Pseudonocardia* strains from the environment. Current models of *Pseudonocardia*/disease coevolution need to be re-examined in light of these new findings.

Multiple lines of evidence shown that a black yeast, closely related to the genus *Phialophora* (Ascomycota), is the fifth symbiont to be recognized in the fungus-growing attine ant/microbe symbiosis (Little and Currie, 2007). The black yeasts, which form a monophyletic group, grow on the ants' cuticle and derive nutrients from the pseudonocardial symbiont (Little and Currie, 2008). Ants infected with black yeasts are significantly less effective at defending their fungal gardens from *Escovopsis*. It is possible that the reduction of mutualistic actinobacterial biomass in ants, probably caused by the black yeast symbionts, reduces the quantity of antibiotics available to inhibit the garden symbiont. However, the reduction in the ability of ants to inhibit *Escovopsis* indicates that it is an integral component of a complex symbiotic association which is not fully understood. Nevertheless, it seems clear that each member of the fungus-growing ant community is directly and/or indirectly influenced by the other partners in both positive and negative ways (Little and Currie, 2008; Poulsen and Currie, 2006).

Enrichment and isolation procedures

Most *Pseudonocardia* species have been isolated on nutrient-poor media under aerobic conditions at 20–30°C. Several species, including *Pseudonocardia xinjiangensis* and *Pseudonocardia yunnanensis*, have been recovered from soil samples collected from Xinjiang and Yunnan Provinces in China following inoculation of soil suspensions onto AV (Nonomura and Ohara, 1971) and HV (Hayakawa, 1990) agars and incubation at 28°C for 21–28 d (Xu et al., 1999). *Pseudonocardia ailaonensis* and *Pseudonocardia zijingensis* were also isolated from Yunnan soil samples, albeit on starch-casein and yeast extract-starch agars, respectively (Huang et al., 2002; Qin et al., 2008b). Similarly, *Pseudonocardia antarctica* was isolated on yeast extract-peptone agar (Prabahar et al., 2004a), and *Pseudonocardia kongjuensis* and *Pseudonocardia spinosispora* were isolated on tap water agar (Lee et al., 2001, 2002). *Pseudonocardia ammonioxydans* was isolated on a modified nitrifying medium inoculated with a coastal sediment suspension prior to incubation at 30°C for a month (Liu et al., 2006), and *Pseudonocardia oroxyli* was recovered from sterile root samples inoculated onto BL-2 agar plates supplemented with penicillin and incubated at 27°C for up to 4 weeks (Gu et al., 2006).

The remaining *Pseudonocardia* species that oxidize hydrocarbons or deleterious organic compounds can be selectively isolated either by enrichment culture or by plating suspensions onto media containing selected compounds as sole carbon sources. *Pseudonocardia asaccharolytica* and *Pseudonocardia sulfidoxydans* were isolated from samples enriched with methyl sulfide-containing gas (Reichert et al., 1998), *Pseudonocardia carboxydivorans* from soil enriched with low concentrations of CO (Park et al., 2008), and *Pseudonocardia chloroethenivorans* by using trichloroethene-contaminated air with phenol as a source

of carbon for energy and growth (Lee et al., 2004). Similarly, *Pseudonocardia benzenivorans* was isolated on a medium containing 1,2,3,5-tetrachlorobenzene as a sole carbon source (Kämpfer and Kroppenstedt, 2004), *Pseudonocardia dioxanivorans* on a basal medium supplemented with THF and yeast extract (Parales et al., 1994), *Pseudonocardia nitrificans* on tap-water agar supplemented with urethan and trace metal salts (Schatz et al., 1954), and *Pseudonocardia tetrahydrofuranoxydans* on a medium enriched with THF (Kohlweyer et al., 2000). *Pseudonocardia petroleophila* and *Pseudonocardia saturnea* strains were isolated using CO_2 enrichments of mineral salts solutions seeded with compost (Hirsch, 1960), and *Pseudonocardia carboxydivorans* was isolated from soil enriched with low concentrations of CO (Park et al., 2008). *Pseudonocardia hydrocarbonoxydans* was isolated as an aerial contaminant on a silica gel plate (Nolof and Hirsch, 1962).

The type strain of *Pseudonocardia autotrophica* was isolated as an airborne contaminant of phosphate buffer that had been left standing next to a coal gas leak (Hirsch, 1960; Takamiya and Tubaki, 1956). *Pseudonocardia autotrophica*, in common with other autotrophic *Pseudonocardia* species, grows faster under heterotrophic conditions. Strains of *Pseudonocardia autotrophica*, "*Amycolata* (i.e. *Pseudonocardia*) *autotrophica* subsp. *amethystina*" and "*Amycolata* (i.e. *Pseudonocardia*) *autotrophica* subsp. *canberrica*" were isolated from suspensions of eucalyptus forest soil, lake side sand, and lake bottom mud using heterotrophic media supplemented with selective agents (Okazaki et al., 1983).

Henssen (1957) isolated the type strain of *Pseudonocardia thermophila* from fresh and rotten manure using a nutrient medium supplemented with cellulose dextrin as a carbon source (Fuller and Norman, 1942). The exact composition of this nutrient medium is not entirely clear from the original paper, however, as a number of variations were used. Subsequently, large numbers of *Pseudonocardia thermophila* strains were isolated from the heating phase of composting cattle manure after 20 d at 45°C on a cellulose medium supplemented with streptomycin sulfate (Goddon and Penninckx, 1984). *Pseudonocardia composta* and *Pseudonocardia spinosa* have been isolated from soil using nutrient-poor media, such as soil extract agar, and incubated at 20–30°C (Henssen, 1989; Henssen and Schäfer, 1971).

Maintenance procedures

Working cultures of *Pseudonocardia* can be maintained at 4°C on appropriate standard media. Long-term preservation of strains is best achieved as frozen stocks in 20% (v/v) aqueous glycerol at −20°C, −80°C (mechanical freezer), or −172°C (liquid nitrogen vapor phase), or by traditional lyophilization procedures.

Procedures for testing special characters

Two pairs of genus specific oligonucleotide primers, AMP3 (5′-GCGGCACAGAGACCGTGGAAT-3′)/AMP2 (5′-GTGGAAA GTTTTTTCGGCTGGGG-3′) and AMP4 (5′-GCGGCACAGAAA CCGTGGAAT-3′)/AMP5 (5′-GTGGAAAGTTTTTTCGGTGGG GG-3′), can be used to identify members of the genus *Pseudonocardia* at annealing temperatures of 53 and 60°C respectively (Morón et al., 1999). The amplification conditions are: initial denaturation at 95°C for 4 min; 40 cycles of 30 s at 93°C, 30 s at 53°C for primer set AMP3/AMP2 or 30 s at 60°C for primer set AMP4/AMP5, and 2 min at 72°C; followed by 10 min at 72°C. Both primers sets yield a 640 bp genus-specific amplification product. The AMP3/AMP2 primer set is particularly effective for the detection and identification of *Pseudonocardia* strains at a lower annealing temperature.

Differentiation of the genus *Pseudonocardia* from other genera

The genus *Pseudonocardia* can be distinguished from other genera classified in the family *Pseudonocardiaceae* by using a combination of chemotaxonomic and morphological criteria (see Table 228 in the treatment of the family *Pseudonocardiaceae*). It also forms a distinct clade in the *Pseudonocardiaceae* 16S rRNA gene tree and can be distinguished from the phylogenetically close genera *Actinomycetospora* and *Kibdelosporangium* (Figure 278) as they contain MK-9(H_4) as the predominant isoprenologue and form pseudosporangia (*Kibdelosporangium*) or no aerial mycelium (*Actinomycetospora*). *Pseudonocardia* strains can also be recognized using genus-specific oligonucleotide primer sets (Morón et al., 1999) and can be distinguished from other genera classified in the family *Pseudonocardiaceae* based on partial amino acid sequencing of ribosomal AT-L30 proteins (Ochi, 1995).

Taxonomic comments

The genus *Pseudonocardia* was proposed to accommodate *Pseudonocardia thermophila*, a moderately thermophilic organism that showed distinctive morphological properties (Henssen, 1957). Morphologically similar strains were designated *Pseudonocardia compacta* (Henssen, 1957) and *Pseudonocardia spinosa* (Henssen and D. Schäfer, 1971; Schäfer, 1969). Another thermophilic organism, "*Pseudonocardia thermospinosa*", was isolated from soil samples from Hanoi, Vietnam (Lu and Yan, 1978), but the name was not validly published. The three species with validly published names could be distinguished from members of other genera of actinomycetes which formed aerial spores in chains by exhibiting acropetal budding of substrate and aerial hyphae (Henssen, 1970; Henssen and Schäfer, 1971; Henssen and Schnepf, 1967), and by forming a two-layered wall and interspace septa (Henssen et al., 1981). However, most of the 29 species with validly published names assigned to the genus have been circumscribed using a combination of genotypic and phenotypic properties. These taxa include species that were previously classified in the genera *Actinobispora* (Xu et al., 1999), *Amycolata* (Lechevalier et al., 1986), and *Pseudoamycolata* (Akimov et al., 1989).

The genus *Actinobispora* was proposed to encompass members of a single species, *Actinobispora yunnanensis*, which formed spores in longitudinal pairs on vegetative hyphae, in longitudinal pairs or singly on aerial hyphae, and which contained *meso*-A_2pm as the wall diamino acid, arabinose, galactose and xylose in whole-organism hydrolysates (an unusual wall chemotype IV), phosphatidylethanolamine and glucosamine-containing phospholipids (phospholipid type 1), and MK-7(H_2) and MK-9(H_2) as predominant isoprenologues, but lacked mycolic acids (Jiang et al., 1991). Subsequently, three additional species, *Actinobispora alaniniphila*, *Actinobispora aurantiaca*, and *Actinobispora xinjiangensis*, were described (Xu et al., 1999). Suzuki et al. (1998) selectively isolated *Actinobispora* strains on gellan gum plates. Huang et al. (2002) found that *Actinobispora* and *Pseudonocardia* species were intermixed in a distinct clade in the *Pseudonocardiaceae* 16S rRNA gene tree, shared key chemical markers, and gave a taxon-specific amplification product using PCR primers designed to differentiate the genus *Pseudonocardia* from related taxa. They also found that the type strains of the

original *Actinobispora* species contained MK-8(H_4) as the major isoprenologue. Huang and her colleagues proposed that the genus *Actinobispora* should become a junior synonym of the genus *Pseudonocardia* and that *Actinobispora alaniniphila*, *Actinobispora aurantiaca*, *Actinobispora xinjiangensis*, and *Actinobispora yunnanensis* be transferred to this genus.

The genus *Amycolata* was proposed by Lechevalier et al. (1986) for a group of actinomycetes that formed substrate hyphae that tended to fragment into squarish subunits, and aerial hyphae which, when formed, were either sterile or fragmented into chains of squarish to oval elements or spore-like structures. The organisms had a wall chemotype IV, a type III phospholipid pattern, and MK-8(H_2, H_4) as predominant isoprenologues, but lacked mycolic acids. The genus provided a taxonomic home for organisms that had previously been misclassified in the genera *Nocardia* and *Streptomyces*. The type species, *Amycolata autotrophica*, included strains previously classified as *Nocardia autotrophica* (Hirsch, 1960) or "*Streptomyces autotrophicus*" (Takamiya and Tubaki, 1956), and also encompassed some strains of *Nocardia coeliaca* (Gordon et al., 1974). *Amycolata autotrophica* strains isolated from root nodules and rhizospheres of *Alnus* species were reclassified as *Amycolata alni* following DNA–DNA pairing studies (Evtushenko et al., 1989). Similarly, *Amycolata hydrocarbonoxydans* and *Amycolata saturnea* were initially described as *Nocardia* species by Nolof and Hirsch (1962) and Hirsch (1960), respectively. "*Streptomyces nitrificans*" and "*Nocardia petroleophila*" were also considered to be species of *Amycolata* based on 16S rRNA gene sequence data (Embley, 1992). Two subspecies of *Amycolata autotrophica* have been described but their names have not been validly published, namely "*Amycolata autotrophica* subsp. *amethystine*" and "*Amycolata autotrophica* subsp. *canberrica*".

In an extensive phylogenetic study of the family *Pseudonocardiaceae*, Warwick et al. (1994) found that the 16S rRNA gene sequences of the type strains of *Amycolata* and *Pseudonocardia* species formed a mixed, but distinct, phyletic branch. These results were in line with those from previous studies which showed that members of these genera contained phosphatidylcholine as a diagnostic phospholipid (Embley et al., 1988b; Lechevalier et al., 1977a, 1986), MK-8(H_4) as the predominant isoprenologue (Embley et al., 1988b; Lechevalier et al., 1986), formed a characteristic electron-dense layer in the substrate and aerial mycelia (Kothe et al., 1989), and contained ribosomal AT-130 proteins that had very similar electrophoretic mobilities (Ochi and Yoshida, 1991) and partial amino acid sequences (Ochi, 1995). Consequently, they proposed that the genus *Amycolata* Lechevalier et al. (1986) be recognized as a junior synonym of the genus *Pseudonocardia* Henssen (1957); they also provided an emended description of the genus, and proposed that *Amycolata alni*, *Amycolata autotrophica*, *Amycolata hydrocarbonoxydans*, *Amycolata saturnea*, "*Nocardia petroleophila*" and "*Streptomyces nitrificans*" be transferred to the genus *Pseudonocardia*.

The monospecific genus *Pseudoamycolata* was proposed for two strains that had previously been classified as *Amycolata autotrophica* (Akimov et al., 1989). The strains resembled *Amycolata* species in overall morphology and phenotype, and contained MK-8(H_4) as the major isoprenologue, but lacked phosphatidylcholine, the absence of which was judged to be sufficient to justify the proposal for a new genus. McVeigh et al. (1994) found that apart from the absence of phosphatidylcholine, *Pseudoamycolata halophobica* resembled *Pseudonocardia* species with respect to cultural, morphological, and physiological properties. They also noted that bacteria synthesized phosphatidylcholine by sequential methylation of phosphatidylethanolamine and speculated that minor mutations might prevent this transformation. These considerations led them to propose that *Pseudoamycolata halophobica* be reclassified in the genus *Pseudonocardia* as *Pseudonocardia halophobica*.

Nearly all of the *Pseudonocardia* species with validly published names form distinct phyletic lines in the *Pseudonocardia* 16S rRNA gene tree (Figure 278). However, comparative taxonomic studies, including DNA–DNA relatedness experiments, are needed to determine whether *Pseudonocardia chloroethenivorans* and *Pseudonocardia dioxanivorans* are distinct species as the type strains of these taxa have identical 16S rRNA gene sequences. The position of *Pseudonocardia spinosa* in the *Pseudonocardia* 16S rRNA tree remains to be established. It has been reported that the type strain of this organism is no longer extant (Embley, 1992), but this is not so as the strain is held in the JCM and NBRC collections.

Improvements in the classification of wall chemotype IV actinomycetes that lack mycolic acids have helped to clarify the taxonomy of the genus *Pseudonocardia* (Embley et al., 1988a, 1988b; Embley, 1992; Goodfellow et al., 1989b; Warwick et al., 1994) and have thereby facilitated the recognition and description of novel species (Gu et al., 2006; Kämpfer et al., 2006; Liu et al., 2006). The improved taxonomy also led to the reclassification of some species previously assigned to the genus. Ōmura et al. (1983) proposed *Pseudonocardia azurea* for an organism that produced two water-soluble antibiotics, azureamycin A and B (Ōmura et al., 1979). This organism was considered to show acropetal budding, as was "*Pseudonocardia fastidiosa*", which produced a macrobicyclic peptide antibiotic (Celmer et al., 1977). Henssen et al. (1987) were unable to confirm that these organisms exhibited acropetal budding, but did find that they had chemotaxonomic and morphological properties consistent with their reclassification in the genus *Amycolatopsis*, as *Amycolatopsis azurea* and *Amycolatopsis fastidiosa*.

It is clear that additional *Pseudonocardia* species remain to be described as it is evident that the genus is underspeciated (Bredholdt et al., 2007; Morón et al., 1999; Schabereiter-Gurtner et al., 2001; Song et al., 2001; Zhang et al., 2008a). It seems likely that the isolation of additional novel pseudonocardiae will be facilitated by the application of innovative selective isolation procedures (Li et al., 2002).

Differentiation of the species of the genus *Pseudonocardia*

The chemotaxonomic, morphological, and physiological properties shown in Table 229 can be used to distinguish between species of *Pseudonocardia*, but members of these taxa have yet to be examined using a common set of tests. The type strains of all but two *Pseudonocardia* species can be separated based on their 16S rRNA gene sequences and phylogeny, as seen in Figure 278.

Acknowledgements

The authors thank Dr T. Kudo (JCM) for providing the type strain of *Pseudonocardia spinosa*, and Dr J.P. Euzéby for clarifying the etymology of *Pseudonocardia nitrificans*. We are particularly indebted to Dr D.P. Labeda (USDA, Peoria) for critically reading our initial manuscript and thereby making many helpful suggestions on how it could be improved.

List of species of the genus *Pseudonocardia*

1. **Pseudonocardia thermophila** Henssen 1957, 408[VP]

ther.mo′phi.la. Gr. n. *thermê* heat; Gr. adj. *philus* loving; N.L. fem. adj. *thermophila* heat loving.

Substrate hyphae are septate, often zig-zag shaped; swellings are usually present and become divided by transverse and longitudinal septa. Aerial hyphae are often zig-zag shaped, young stages with constrictions; later on they are septate throughout; swellings are rarely present. Spores on substrate and aerial mycelium are formed by budding or secondary septation of hyphal segments. The inner wall layer in hyphae and spores is uniformly thin and is not thickened in mature spores. Good growth occurs on nutrient and yeast agars. Colonies are yellow and covered by thick white aerial hyphae. Good growth also occurs on asparagine-glycerol and yeast-glucose agars; colonies are yellow and covered by sparse aerial hyphae. Does not grow on oatmeal agar. Grows between at 28 and 60°C (optimally between 40 and 50°C).

Casein and starch are degraded, but not gelatin. H_2S is produced. Acid is produced from galactose, inositol, maltose, melezitose, and 1,2-propanediol, but not from mannose, methyl α-D-glucoside, or sucrose. Additional phenotypic features are shown in Table 229.

Source: isolated from fresh and rotten manure.

DNA G+C content (mol%): not determined.

Type strain: strain MB A-18, ATCC 19285, CBS 277.66, DSM 43832, JCM 3095, NBRC 15559, VKM Ac-896.

Sequence accession no. (16S rRNA gene): X53195.

2. **Pseudonocardia ailaonensis** Qin, Su, Zhang, Wang, Jiang, Xu and Li 2008b, 2088[VP]

ai.la.o.nen′sis. N.L. fem. adj. *ailaonensis* pertaining to Ailao Mountain, Yunnan province, China, the source of the soil sample from which the type strain was isolated.

Forms substrate hyphae that fragment into rod-shaped elements and aerial hyphae that differentiate into long chains of smooth-walled rod-shaped spores. Cream-white aerial hyphae are formed on Czapek, glucose-asparagine, potato, and yeast extract-malt extract agars. The color of the substrate mycelium is orange-yellow on Czapek agar, yellow-brown on glucose-asparagine, and deep orange-yellow on yeast extract-malt extract and potato agars; does not form diffusible pigments on any of these media. Melanin pigments are produced on peptone-yeast extract-iron agar. Grows between 15 and 37°C (optimum at 28°C). The pH range for growth is 6.0–8.0.

Does not liquefy gelatin, produce H_2S, lecithinase, or degrade either cellulose or starch. Milk is coagulated and peptonized. Reduces nitrate. Acid is produced from dulcitol (weak), galactose, glycerol, mannose, and sucrose, but not from inositol, D-lactulose, melezitose, methyl-D-glucoside, or raffinose. Grows on cellobiose, inositol, lactose, mannitol, melezitose (weak), oxalate, ribose, sorbitol, and sucrose as sole carbon sources, but not on acetate, galactose, or xylose. L-Arginine, L-cysteine, L-ornithine, L-threonine, and L-tyrosine are used as sole carbon sources.

The predominant fatty acids are $C_{16:0}$ iso (35.5%), $C_{16:0}$ iso 2-OH (10.8%), and $C_{16:0}$ 10-methyl (9.0%). The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidylglycerol, and phosphatidylinositol.

Source: the type strain was isolated from a soil sample collected from Ailao Mountain in Yunnan Province, south-west China.

DNA G+C content (mol%): 74.1 (HPLC).

Type strain: strain YIM 45505, DSM 44979, KCTC 19315.

Sequence accession no. (16S rRNA gene): DQ344632.

3. **Pseudonocardia alaniniphila** (Xu, Jin, Mao, Lu, Cui and Jiang 1999) Huang, Wang, Lu, Hong, Liu, Tan and Goodfellow 2002, 981[VP] (Basonym: *Actinobispora alaniniphila* Xu, Jin, Mao, Lu, Cui and Jiang 1999, 885)

a.la.ni.ni′phi.la. N.L. n. *alaninum* alanine; Gr. adj. *philus* loving; N.L. fem. adj. *alaniniphila* alanine loving.

Forms substrate and aerial hyphae that are branched, but which do not fragment. Spores are borne in longitudinal pairs on vegetative hyphae and either singly or in longitudinal pairs on aerial hyphae at 45°C. Substrate hyphae are orange-yellowish and aerial hyphae are sparse and pink-white. Neither diffusible nor melanin pigments are produced. Does not grow at 45°C.

Pectin is degraded, but not cellulose or starch. Nitrate is reduced. Does not produce H_2S. Cells utilize D-fructose, L-rhamnose, D-xylose, D-mannitol, alanine, L-histidine, and proline, but not adonitol cellobiose, raffinose, or inulin. Acid is not produced from these carbon sources. Alanine, L-histidine, and proline are used as sources of nitrogen. Resistant to neomycin and rifampicin (each at 50 μg/ml). Weak antifungal activity is shown against *Aspergillus niger*. Additional phenotypic features are shown in Table 229.

The cellular polar lipid pattern contains phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylmethylethanolamine, and glucosamine-containing phospholipids.

Source: the type strain was isolated from a soil sample collected at Xichou, Yunnan Province, China.

DNA G+C content (mol%): 69.3 (T_m).

Type strain: strain Y-16303, CCTCC AA 97001, CGMCC 4.1536, DSM 44660, JCM 11837.

Sequence accession no. (16S rRNA gene): EU722519.

4. **Pseudonocardia alni** (Evtushenko, Akimov, Dobritsa and Taptykova 1989) Warwick, Bowen, McVeigh and Embley 1994, 298[VP] (Basonym: *Amycolata alni* Evtushenko, Akimov, Dobritsa and Taptykova 1989, 76)

al′ni. L. gen. n. *alni* of alder, referring to the isolation of the type strain and some other strains from alder associations.

Substrate and aerial mycelia fragment into rod-shaped and oval elements. Abundant chains of spores (up to 1.5 μm in diameter) are formed on aerial hyphae. Substrate hyphae are characterized by the presence of swellings, polygonal shaped cells, and their conglomerates. Swollen hyphal segments (up to 2.5 μm in diameter and 10 μm long) are present and become divided by transverse and longitudinal septa. The aerial mycelium is white to cream colored and the substrate mycelium is orange to brown. Moderate growth occurs on water agar.

Degrades gelatin, starch, and Tweens 40, 60 and 80, but not casein or cellulose. Esculin is hydrolyzed, but not allantoin. Acid is produced from D-arabinose, fructose, galactose,

glycerol, methyl α-D-glucoside, 1,2-propanediol, ribose, and sucrose, but not from dulcitol, galactose, inositol, inulin, mannose, melezitose, rhamnose, ribose, or sucrose. Acetate, aconitate, benzoate, citrate, formate, fumarate, 2-oxoglutarate, lactate, malate, maleate, propionate, pyruvate, sebacate, succinate, and *trans*-aconitate are assimilated. Arginine, asparagine, glutamine, histidine, leucine, ornithine, and proline are used as nitrogen sources. Grows in the presence of phenol (0.001%, w/v) and thymol (0.01%, w/v). Susceptible (μg/ml) to chloramphenicol (32), fucidin (10), gentamicin (4), kanamycin (16), lysozyme (50), monomycin (8), nalidixic acid (64), neomycin (4), novobiocin (0.25), rifampin (0.125), roseofungin (10), streptomycin (4), tetracycline (1), and vancomycin (0.5), but resistant to ampicillin (1–16), benzylpenicillin (0.5–10), carbenicillin (1–10), ristomycin (0.05), tobramycin (5), and vancomycin (0.25). Additional phenotypic features are shown in Table 229.

The major fatty acids are $C_{16:0}$ iso (36–40%) and $C_{17:0}$ anteiso acid (14–19%); also contains smaller amounts of $C_{16:1}$ iso (5.8–8.6%), $C_{16:0}$ (3.8–8.1%), $C_{17:0}$ iso (4.4–14.4%), $C_{17:0}$ (4.5–9.6%), $C_{18:0}$ methyl (3.5–6.9%), and $C_{18:0}$ anteiso (1.2–7.5). The cellular polar lipid pattern contains phosphatidycholine and phosphatidylethanolamine.

Source: isolated from root nodules and rhizospheres of alders [*Alnus glutionosa* (L.) Gaerth. and *Alnus incana* (L.) Moench.], and from marine sediments.

DNA G+C content (mol%): 72–74 (T_m).

Type strain: strain 3LS, DSM 44104, IFO (now NBRC) 14991, JCM 9103, NBRC 14991, VKM Ac-901.

Sequence accession no. (16S rRNA gene): AJ252823.

5. **Pseudonocardia ammonioxydans** Liu, Wu, Liu and Liu 2006, 556[VP]

am.mo.ni.o.xy′dans. N.L. n. *ammonia* ammonia; N.L. part. adj. *oxydans* oxidizing; N.L. part. adj. *ammonioxydans* oxidizing ammonia.

Forms aerial and substrate mycelia which fragment into rod-shaped elements. Short chains of smooth-surfaced spores are formed on the substrate mycelium by acropetal budding. A brown substrate mycelium and a white aerial mycelium are formed on Luria–Bertani and trypticase soy broth agars. Grows between 4 and 40°C.

Ammonia is oxidized to nitrate in a modified nitrifying medium (nitrification in MNM broth) and in blends of MNM and Luria–Bertani media (dissimilatory, heterotrophic ammonia oxidation). Degrades casein, gelatin (weak), and starch (weak). Produces H_2S. Acid is produced from *N*-acetyl-D-glucosamine, D-arabitol, D-galacturonic acid, gluconic acid, glycerol, 1,2-propanediol, and ribose, but not from *N*-acetyl-β-D-mannosamine, arbutin, L-fucose, D-tagatose, gentiobiose, inositol, α-D-lactose, lactulose, maltotriose, mannose, methyl α-D-galactoside, methyl β-D-galactoside, methyl α-D-glucoside, methyl α-D-mannoside, melezitose, palatinose, D-psicose, raffinose, sucrose, turanose, or xylitol.

Growth occurs in the presence of 0–8% NaCl, with optimal growth at 3.5% NaCl. Additional phenotypic features are shown in Table 229.

The major fatty acids are $C_{16:0}$ iso (41.1%), $C_{16:1}$ iso (15.7%), and $C_{17:1}$ ω8*c* (12.1%). The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidylcholine, phosphatidylglycerol, phosphatidylinositol mannosides, and phosphatidylmethylethanolamine, but not glucosamine-containing phospholipids.

Source: the type strain was isolated from coastal sediment collected from the Jiao-Dong peninsula, near Qingdao, Shandong Province, China.

DNA G+C content (mol%): 69.6 (T_m).

Type strain: strain H9, CGMCC 4.1877, JCM 12462.

Sequence accession no. (16S rRNA gene): AY500143.

Further comments: metabolizes diverse carbon compounds on Biolog GP2 microplates (Liu et al., 2006).

6. **Pseudonocardia antarctica** Prabahar, Dube, Reddy and Shivaji 2004b, 1005[VP] (Effective publication: Prabahar, Dube, Reddy and Shivaji 2004a, 69.)

an.tarc′ti.ca. L. fem. adj. *antarctica* southern, and by extension, pertaining to the continent Antarctica.

Filamentous brown substrate and aerial mycelia form a white conglomerate. Spores are formed by fragmentation of aerial hyphae. Grows at 7–38°C (optimum at 25°C) and pH 4–10. β-Galactosidase-, oxidase-, and phosphatase-positive, but negative for arginine dihydrolase, arginine decarboxylase, esculin, lipase, and lysine. Acid is produced from galactose, mannose, and ribose, but not from fructose, inositol, or melezitose.

Resistant to co-trimoxazole, nalidixic acid, and norfloxacin. Additional phenotypic features are shown in Table 229.

The major fatty acids are $C_{16:0}$ iso (30%) and $C_{16:0}$ (15%). The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylmethylethanolamine.

Source: isolated from a moraine sample collected from the McMurdo Dry Valleys region of Antarctica.

DNA G+C content (mol%): 71 (T_m).

Type strain: strain DVS 5a1, DSM 44749, JCM 12172, MTCC 4297.

Sequence accession no. (16S rRNA gene): AJ576010.

Further comments: the specific epithet *antarctica* is a L. adj. not a N.L. adj. as cited in the paper by Prabahar et al. (2004a).

7. **Pseudonocardia asaccharolytica** Reichert, Lipski, Pradella, Stackebrandt and Altendorf 1998, 447[VP]

a.sac.cha.ro.ly′ti.ca. Gr. pref. *a* not; Gr. n. *sakchâr* sugar; Gr. fem. adj. *lutikê* able to dissolve, able to loosen; N.L. fem. adj. *asaccharolytica* referring to the failure to produce acid from carbohydrates.

Substrate hyphae are yellow on trypticase soy agar and fragment into coccoid and rod-shaped elements. Swollen hyphal segments up to 2 μm in diameter are formed, as are transverse hyphal septa. White, aerial hyphae carry long chains of oval spores. Spore surfaces are smooth. Dimethyl disulfide is oxidized. Acid is produced from 1,2-propanediol, but not from galactose, inositol, mannose, melezitose, methyl α-D-glucoside, sucrose, or xylitol. Additional phenotypic features are shown in Table 229.

The major fatty acids are $C_{16:0}$ iso (21.5–28.1%), $C_{16:0}$ (19.3–23.3%), $C_{17:0}$ iso (11.6–12.7%), $C_{15:0}$ iso (8.2–11.4%), and $C_{17:0}$ anteiso (4.8–6.1%); also contains small amounts of 10-methyl fatty acids. Mycolic acids are not formed. The cellular polar lipid pattern contains diphosphatidylglycerol, hydroxyphosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, phosphatidylmethylethanolamine, and a ninhydrin-positive component.

Source: isolated from tree-bark compost biofilters from an animal-rendering plant.

DNA G+C content (mol%): not determined.

Type strain: strain 580, CIP 105685, DSM 44247, IFO (now NRBC) 16224, JCM 10410.

Sequence accession no. (16S rRNA gene): Y08536.

8. **Pseudonocardia aurantiaca** (Xu, Jin, Mao, Lu, Cui and Jiang 1999) Huang, Wang, Lu, Hong, Liu, Tan and Goodfellow 2002, 981[VP] (Basonym: *Actinobispora aurantiaca* Xu, Jin, Mao, Lu, Cui and Jiang 1999, 885.)

au.ran.ti′a.ca. N.L. fem. adj. *aurantiaca* orange-colored.

Forms substrate and aerial hyphae that are branched, but do not fragment. Spores are borne in longitudinal pairs on vegetative hyphae and either singly or in longitudinal pairs on aerial hyphae. The substrate mycelium is orange to orange-yellow and is covered by sparse, pink-white aerial hyphae. A brilliant yellow diffusible pigment is produced on oatmeal agar. Melanin pigments are formed. Does not grow at 45°C.

Pectin is degraded, but not cellulose or starch. Gelatin is liquefied. Milk is neither coagulated nor peptonized. Does not produce H_2S, lecithinase, or reduce nitrate. Cellulose, fructose, raffinose, and rhamnose are used as sole carbon sources, but not adonitol, inositol, mannitol, or xylose. Acid is not produced from these sugars. Alanine, L-histidine, and proline are used as sole nitrogen sources.

Shows weak antimicrobial activity against *Bacillus subtilis.* Resistant to neomycin, but not to rifampin (each at 50 µg/ml). Additional phenotypic features are shown in Table 229.

The cellular polar lipid pattern contains phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, and glucosamine-containing phospholipids.

Source: the type strain was isolated from a soil sample collected at Jianchuan, Yunnan Province, China.

DNA G+C content (mol%): 71.5 (T_m).

Type strain: strain Y-14860, CCTCC AA 97002, CGMCC 4.1537, JCM 11838.

Sequence accession no. (16S rRNA gene): AF056707.

9. **Pseudonocardia autotrophica** (Takamiya and Tubaki 1956) Warwick, Bowen, McVeigh and Embley 1994, 298[VP] [Basonym: *Nocardia autotrophica* Hirsch 1961, 362; "*Streptomyces autotrophicus*" Takamiya and Tubaki 1956, 59; *Amycolata autotrophica* (Takamiya and Tubaki 1956) Lechevalier, Prauser, Labeda and Ruan 1986, 34]

au.to.tro′phi.ca. Gr. pron. *autos* himself; N.L. fem. adj. *trophica* (from Gr. fem. adj. *trophikê*) nursing, tending or feeding; N.L. fem. adj. *autotrophica* self-nourishing, referring to the ability to grow at the expense of H_2 and CO_2.

Yellow to brown substrate hyphae fragment into squarish spores of unequal size, especially in liquid media. White to cream aerial hyphae differentiate into long chains of cylindrical to oval spores. Zig-zag mycelial growth and swollen hyphal segments are formed. Longitudinal and transverse septa are formed in the mycelium. Grows at 10–37°C, but not at 42°C. Autotrophic. Hydrogen is utilized in the presence of oxygen and carbon dioxide in a mineral salts medium.

Decarboxylates acetate, citrate, lactate, malate, propionate, pyruvate, and succinate, but not benzoate, mucate, oxalate, or tartrate. Produces phosphatase and H_2S. Does not hydrolyze esculin. Degrades testosterone, and Tweens 20, 40, 60 and 80, but not casein, gelatin, or starch. Acid is produced from galactose, inositol, mannose, melezitose, methyl α-D-glucoside, 1,2-propanediol, and sucrose.

Does not grow in lysozyme, or salicylate broth. Susceptible to (µg/ml) gentamicin (50), minocycline (50), rifampin (50), streptomycin (50), and vancomycin (50), but is resistant to erythromycin (50), fusidic acid (50), penicillin (10 IU). Additional phenotypic features are shown in Table 229.

The major fatty acids are $C_{16:0}$ iso (33.5%), $C_{17:0}$ iso (7.4%), and $C_{17:0}$ ω-methyl (10%). The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidylcholine, phosphatidylglycerol, phosphatidylinositol, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannoside, and phosphatidylmethylethanolamine, but not phosphatidylethanolamine.

Source: isolated from phosphate buffer solution, aluminum hydroxide gel, vegetable matter, soil, and clinical specimens.

DNA G+C content (mol%): 70 (T_m).

Type strain: ATCC 19727, CIP 107114, DSM 535, IFO (now NRBC) 12743, JCM 4348, NRRL B-11275, VKM Ac-941.

Sequence accession no. (16S rRNA gene): AJ252824.

10. **Pseudonocardia benzenivorans** Kämpfer and Kroppenstedt 2004, 751[VP]

ben.ze.ni.vo′rans. N.L. neut. n. *benzenum* benzene; L. part. adj. *vorans* devouring, digesting; N.L. fem. part. adj. *benzenivorans* digesting benzene.

Forms pale substrate hyphae that fragment into rod-shaped and coccoid elements. Aerial mycelium is white. Good growth on R2A and nutrient agars at 25–30°C after incubation for 3 d. Does not grow at 4–20 or 40–55°C. L-Alanine-*p*-nitroanilide (NA), *p*-nitrophenyl-(NP)-α-D-glucopyranoside, *p*NP-phenylphosphonate (weak), *bis*-*p*NP-phosphate, and L-proline-*p*NA are hydrolyzed, but not esculin, 2-deoxythymidine-5′-*p*NP-phosphate, *o*NP-β-D-galactopyranoside, *p*NP-β-D-glucopyranoside, L-glutamate-3-carboxy-*p*NA, *p*NP-phosphorylcholine, proline-*p*NA, or *p*NP-α-D-xylopyranoside. Acid is produced from galactose, glycerol, D-lactulose, and mannose, but not from dulcitol, inositol, melezitose, methyl α-D-glucoside, raffinose, sorbose, or sucrose. Grows on 4-aminobutyrate and 4-hydroxybutyrate (each at 10 mM). Additional phenotypic features are shown in Table 229.

The predominant fatty acids are $C_{16:0}$ iso (52.1%), $C_{16:1}$ iso *cis*9 (6.0%), $C_{17:0}$ iso (6.9%), $C_{17:1}$ *cis*9 (5.2%), and $C_{17:0}$

10-methyl (5.5%); small amounts of methyl-branched fatty acids are also present. The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidylethanolamine, and phosphatidylinositol, but not phosphatidylcholine.

Source: the type strain, which originated from a soil sample collected in Bitterfeld, Germany, was isolated from an enrichment culture containing 1,2,3,5-tetrachlorobenzene as the sole source of carbon.

DNA G+C content (mol%): not determined.

Type strain: strain B5, CCUG 49018, CIP 107928, DSM 44703, JCM 12694.

Sequence accession no. (16S rRNA gene): AJ556156.

Further comments: metabolizes a diverse range of carbon compounds on Biolog GP2 microplates (Kämpfer and Kroppenstedt, 2004)

11. **Pseudonocardia carboxydivorans** Park, Park, Lee and Kim 2008, 2477[VP]

car.bo.xy.di.vo′rans. N.L. neut. n. *carboxydum* carbon monoxide; L. part. adj. *vorans* devouring, digesting; N.L. part. adj. *carboxydivorans* digesting carbon monoxide.

Forms brown substrate mycelium and a white aerial mycelium. The aerial hyphae fragment into rod-shaped elements. Grows optimally at 25°C. Oxidizes carbon monoxide. Does not produce oxidase. Does not degrade gelatin or starch. Acid is produced from inulin, but not from cellobiose, inositol, maltose, mannitol, mannose, melezitose, ribose, trehalose, or xylose. *N*-Acetyl-D-glucosamine, inulin, and mannan are used as sole carbon sources, but not cellobiose, fructose, galactose, *myo*-inositol, maltose, mannitol, mannose, melezitose, raffinose, L-rhamnose, D-ribose, sorbitol, sucrose, trehalose, xylitol, or D-xylose. Additional phenotypic features are shown in Table 229.

The predominant fatty acids are $C_{16:0}$ iso (47.2%) and $C_{16:1}$ iso (22.8%); also contains smaller amounts of $C_{15:0}$ iso (5.0%), $C_{16:1}$ *cis*9 (5.9%), $C_{16:0}$ 10-methyl (4.6%), $C_{17:0}$ iso (3.0%), $C_{17:0}$ anteiso (2.6%), and $C_{17:1}$ *cis*9 (2.4%). The major menaquinone is MK-9.

Source: the type strain was isolated from soil collected at a roadside in Seoul, Korea.

DNA G+C content (mol%): 77 (HPLC).

Type strain: strain Y8, JCM 14827, KCCM 42678.

Sequence accession no. (16S rRNA gene): EF114314.

12. **Pseudonocardia chloroethenivorans** Lee, Strand, Stensel and Herwig 2004, 138[VP]

chlo.ro.e.the.ni.vo′rans. N.L. neut. n. *chloroethenum* chloroethene; L. part. adj. *vorans* devouring; N.L. fem. part. fem. adj. *chloroethenivorans* chloroethene-devouring.

Forms substrate and aerial hyphae that are branched, but do not fragment. Spores are formed at the ends of hyphae. Substrate hyphae are white. Diffusible pigments not formed. Grows on phenol as a source of carbon and energy. Chloroethane, *cis*1,2-dichloroethene, and trichloroethane are degraded. Additional phenotypic features are shown in Table 229.

The major fatty acids are $C_{16:0}$ iso (37.3%), $C_{15:0}$ iso (4.5%), $C_{16:0}$ (5.6%), $C_{16:0}$ 10-methyl (6.1%), $C_{17:0}$ iso (5.9%), $C_{17:0}$ anteiso (6.0%).

Source: the type strain was isolated from an aerobic laboratory enrichment in the Department of Civil and Environmental Engineering, University of Washington, Seattle, WA, USA.

DNA G+C content (mol%): not determined.

Type strain: strain SL-1, ATCC BAA-742, DSM 44698, JCM 12679.

Sequence accession no. (16S rRNA gene): AF454510.

Further comments: metabolizes a wide range of substrates on Biolog GP2 microplates (Lee et al., 2004).

13. **Pseudonocardia compacta** Henssen, Happach-Kasan, Renner and Vobis 1983, 834[VP]

com.pac′ta. L. fem. adj. *compacta* compact.

Substrate hyphae are septate and densely branched; swellings are common and, in part, multidivided. Aerial hyphae are compact, constricted or septate, and show apical and intercalary swellings. Spores of varying shapes and lengths are formed on substrate and aerial mycelia. The inner layer of hyphal walls vary in thickness. The inner layer of spore walls are thick in mature spores. Moderate to good growth occurs on artificial soil agar, with scanty yellow substrate hyphae and abundant white aerial hyphae. Optimum temperature for growth is 20–30°C.

Does not degrade casein, gelatin, or starch. Acid is not formed from galactose, mannose, melezitose, methyl α-D-glucoside, inositol, 1,2-propanediol, sucrose, or xylitol. Additional phenotypic features are shown in Table 229.

The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylinositol mannosides, and phosphatidylmethylethanolamine. The major fatty acids are $C_{16:0}$ iso (34.5%), $C_{15:0}$ (10.0%), and $C_{17:0}$ (4.8%).

Source: isolated from garden soil collected in Wohra, near Marburg, Germany.

DNA G+C content (mol%): not determined.

Type strain: strain MB H-146, ATCC 35407, CBS 160.82, DSM 43592, IFO (now NRBC) 14343, JCM 7438, NRRL B-16170, VKM Ac-897.

Sequence accession no. (16S rRNA gene): AJ252825.

14. **Pseudonocardia dioxanivorans** Mahendra and Alvarez-Cohen 2005, 597[VP]

di.o.xa.ni.vo′rans. N.L. n. *dioxanum* dioxane; L. part. adj. *vorans* devouring; N.L. part. adj. *dioxanivorans* dioxane-devouring.

Forms white aerial hyphae and yellowish branched substrate hyphae which fragment into rod-shaped elements. Hyphal swellings and budding are sometimes observed. Does not form diffusible pigments. Optimal growth temperature is 30°C.

Aerobic autotrophic growth occurs on CO_2 and H_2. Fixes dinitrogen. Grows on 1,3- and 1,4-dioxane, butyl methyl ether, 2-methyl-1,3-dioxolane, THF, and tetrahydropyran. Acid is produced from glycerol, but not from dulcitol, inositol, lactulose, mannose, melezitose, or sucrose. Additional phenotypic features are shown in Table 229.

The major fatty acids are $C_{16:0}$ iso (27.5%), $C_{16:1}$ iso *cis*9 (9.3%), and $C_{17:1}$ iso *cis*9 (23.6%). The predominant menaquinone is MK-8(H_4); also contains a small amount of MK-7(H_4).

Source: isolated from a 1,4-dioxane-contaminated sludge sample collected at Darlington, South Carolina, USA (Parales et al., 1994).

DNA G+C content (mol%): 74 (HPLC).

Type strain: strain CB1190, ATCC 55486, DSM 44775, JCM 13855.

Sequence accession no. (16S rRNA gene): AY340622.

Further comments: metabolizes a diverse range of carbon compounds on Biolog GP2 and SEP2 microplates, and nitrogen sources on Biolog PM3 plates (Mahendra and Alvarez-Cohen, 2005).

15. **Pseudonocardia endophytica** Chen, Qin, Li, Zhang, Xu, Jiang, Kim and Li 2009, 559[VP]

en.do.phy′ti.ca. Gr. *endo* within; Gr. n. *phyton* plant; L. fem. suff. *-ica* adjectival suffix used with the sense of belonging to; N.L. fem. adj. *endophytica* within plant, endophytic, pertaining to the original isolation from plant tissues.

Forms yellowish-brown substrate mycelium and white aerial mycelium on tryptic soy and yeast extract-malt extract agars. The substrate mycelium fragments into rod-shaped elements. Spore chains form on aerial mycelium. Does not form diffusible pigments. Growth occurs at 15–37°C and pH 6.0–8.0.

Catalase-positive and oxidase-negative. Malonate and ornithine decarboxylase tests are positive, but negative for the gluconate test, H_2S production, milk coagulation and peptonization, and nitrate reduction. Does not degrade casein, cellulose, gelatin, or starch. Acid is produced from arbutin, esculin, galactose, glycerol, melezitose, D-ribose, sucrose, trehalose, and turanose, but not from amygdalin, arabitol, dulcitol, fucose, gentiobiose, gluconate, glycogen, inositol, inulin, 2-ketogluconate, lyxose, mannose, melibiose, methyl α-D-glucoside, methyl α-D-mannoside, methyl β-D-xyloside, *N*-acetylglucosamine, raffinose, sorbose, starch, tagatose, or xylitol. Utilizes L-asparagine, L-glutamic acid, *p*-hydroxyphenylacetic acid, α-ketoglutaric acid, α-ketovaleric acid, D-malic acid, *N*-acetyl-L-glutamic acid, propionic acid, putrescine, L-pyroglutamic acid, pyruvic acid, succinamic acid, and succinic acid, but not acetic acid, L-alaninamide, D- or L-alanine, L-alanyl glycine, glycyl L-glutamic acid, α-, β- or γ-hydroxybutyric acid, lactamide, L-lactic acid, L-malic acid, methyl pyruvate, monomethyl succinate, pyruvic acid, or L-serine. Additional phenotypic features are shown in Table 229.

The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, and phosphatidylmethylethanolamine. The major fatty acids are $C_{16:0}$ iso (34.0%), $C_{17:1}$ *cis*9 (14.5%), and $C_{15:0}$ iso (9.6%). The predominant menaquinone is MK-8 (H_4); also contains traces of MK-7(H_6) and MK-9.

Source: isolated from a plant sample collected from Xishuangbanna, Yunnan Province, south-western China.

DNA G+C content (mol%): 70.3 (HPLC).

Type strain: strain YIM 56035, CCTCC AA 206026, DSM 44969, KCTC 19150.

Sequence accession no. (16S rRNA gene): DQ887489.

16. **Pseudonocardia halophobica** (Akimov, Evtushenko and Dobritsa 1989) McVeigh, Munro and Embley 1994, 302[VP] (Basonym: *Pseudoamycolata halophobica* Akimov, Evtushenko and Dobritsa 1989, 460)

ha.lo.pho′bi.ca. Gr. n. *hals* halos salt, the sea; Gr. n. *phobos* fear, dread; L. fem. suff. *-ica* suffix used with the sense of pertaining to; N.L. fem. adj. *halophobica* salt-fearing, referring to the inability to grow in the presence of 3% NaCl.

Forms substrate and aerial hyphae which tend to fragment into rod-shaped and oval elements. Shows zig-zag mycelial growth and longitudinal and transverse hyphal septa. Short chains of spores may be produced on aerial hyphae. Swollen hyphal segments (up to 3 μm long) are formed. The aerial mycelium is white to cream colored and the substrate mycelium ranges from yellowish orange to brown, depending on the medium. An orange substrate mycelium is formed on peptone-yeast extract agar.

Degrades Tweens 40 and 60. Arbutin and esculin are hydrolyzed, but not allantoin. Decarboxylates aconitate, formate, lactate, mannose, malate, propionate, pyruvate, succinate, sebacate, and *trans*-aconitate, but not maleate or salicylate. Gaseous aliphatic hydrocarbons (C6–C14) are used for growth. Grows on 4-aminobutyrate and 4-hydroxybutyrate (each at 10 mM). Acid is produced from inositol and sucrose, but not from dulcitol, glycerol, D-lactulose, mannose, melezitose, methyl α-D-glucoside, raffinose, or sorbose. Alanine, arginine, hydroxyproline, ornithine, phenylalanine, proline, threonine, tryptophan, and valine are used as sole nitrogen sources, but not glycine, histidine, leucine, lysine, or tyrosine.

Susceptible to (μg/ml) fucidin (10), lincomycin (1), methacycline (1), novobiocin (50), penicillin (10), polymyxin B (20), roseofungin (10), and tetracycline (10). Does not grow in the presence of crystal violet (0.000001, w/v); azide (0.001%, w/v) or sodium chloride (3%, w/v). Additional phenotypic features are shown in Table 229.

Major fatty acids are $C_{16:0}$ iso (19–26%), $C_{17:0}$ anteiso (17–21%), and $C_{15:0}$ iso (5.5–9%); also contains smaller amounts of $C_{15:0}$, $C_{16:0}$, $C_{16:1}$, $C_{17:0}$ 10-methyl, and $C_{18:0}$ 10-methyl. The cellular polar lipid pattern contains diphosphatidylglycerol, hydroxyphosphatidylethanolamine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannoside; also contains small amounts of phosphatidylmethylethanolamine and a ninhydrin-positive component, but does not contain either phosphatidylcholine or glucosamine-containing phospholipids.

Source: isolated from soil.

DNA G+C content (mol%): 72 (T_m).

Type strain: strain SS1/1, ATCC 51535, DSM 43089, IFO (now NRBC) 15408, IMRU 1300, JCM 9421, NRRL B-16514, VKM Ac-1069.

Sequence accession no. (16S rRNA gene): AJ252827.

17. **Pseudonocardia hydrocarbonoxydans** (Nolof and Hirsch 1962) Warwick, Bowen, McVeigh and Embley 1994, 298[VP] [Basonym: *Nocardia hydrocarbonoxydans* Nolof and Hirsch 1962, 267; *Amycolata hydrocarbonoxydans* (Nolof and Hirsch 1962) Lechevalier, Prauser, Labeda and Ruan 1986, 34]

hy.dro.car.bo.no′xy.dans. Gr. n. *hudôr* water; L. n. *carbo -onis* coal, charcoal; N.L. part. adj. *oxydans* oxidizing; N.L. pres. part. *hydrocarbonoxydans* oxidizing hydrocarbons.

Zig-zag mycelial growth and swollen hyphal segments are evident. Longitudinal and transverse hyphal septa are formed. Aerial and substrate hyphae may fragment into

squarish elements. Sparse to moderate white aerial hyphae are formed. Aerial hyphae are white and sparse to moderate; substrate hyphae are off-white, yellowish white, gold, or brown depending on the growth medium. Grows at 10–37°C, but not at 45°C.

Gaseous aliphatic hydrocarbons (C6–C14) are used for growth. Grows on 4-aminobutyrate and 4-hydroxybutyrate (each at 10 mM). Positive for catalase, phosphatase, and esculin. Decarboxylates lactate, propionate, and pyruvate, but not benzoate, mucate, or tartrate. Does not degrade casein, or grow in lysozyme or salicylate broths. Acid is produced from inositol and sucrose, but not from dulcitol, glycerol, D-lactulose, mannose, melezitose, methyl α-D-glucoside, raffinose, or sorbose. Additional phenotypic features are shown in Table 229.

L-Alanine-*p*NA, *o*NP-β-galactopyranoside (weak), *p*NP-α- and *p*NP-β-D-glucopyranoside, *p*NP-phenylphosphonate, *bis*-*p*NP-phosphate, L-proline, *p*NA-glucopyranoside, and *p*NP-β-D-xylopyranoside are hydrolyzed, but not 2-deoxythymidine-5′-*p*NP-phosphate, esculin, L-glutamate-γ-3-carboxy-*p*-NA, or *p*NP-phosphorylcholine.

The predominant fatty acids are $C_{15:0}$ iso (10.9%), $C_{16:0}$ iso (30.8%), and $C_{16:0}$ (25.8%). The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidycholine, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, and phosphatidylmethylethanolamine, but not phosphatidylethanolamine. The predominant menaquinones are MK-8(H_2) and MK-8(H_4).

Source: air contaminant; isolated from a silica gel plate.

DNA G+C content (mol%): 69 (T_m).

Type strain: ATCC 15104, DSM 43281, IFO (now NRBC) 14498, JCM 3392, NRRL B-16171, VKM Ac-799.

Sequence accession no. (16S rRNA gene): AJ252826.

Further comments: metabolizes a diverse range of substrates on Biolog GP2 and SFP2 microplates (Mahendra and Alvarez-Cohen, 2005).

18. **Pseudonocardia kongjuensis** Lee, Kim, Min, Lee, Kang and Hah 2001, 1509[VP]

kong.ju.en′sis. N.L. fem. adj. *kongjuensis* of Kongju, Republic of Korea.

Forms an abundant yellowish brown substrate mycelium and a white aerial hyphae mycelium that fragments into rod-shaped spores. The spore surface is smooth. Growth occurs between 4 and 37°C.

Catalase-positive. Produces H_2S. Casein is degraded, but not gelatin or starch. Acid is produced from galactose, glycerol (weak), inositol, mannose, melezitose, and sucrose, but not from 2,3-butanediol, dulcitol, melibiose, methyl α-D-glucoside, methyl α-D-mannoside, 1,2-propanediol, raffinose, sorbose, or D-xylitol. Additional phenotypic features are shown in Table 229.

The major fatty acids are $C_{16:0}$ iso (31.4%), $C_{17:1}$ (13.8%), $C_{18:0}$ (9.6%), $C_{16:1}$ (7.4%), $C_{16:0}$ (6.0%), $C_{16:1}$ iso (6.7%), and $C_{17:1}$ iso (6.2%). The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, and phosphatidylinositol. The predominant menaquinone is MK-8(H_4).

Source: isolated from a gold mine cave in Kongju, Republic of Korea.

DNA G+C content (mol%): 71 (HPLC).

Type strain: strain LM 157, DSM 44525, IMSNU 50583, JCM 11896, KCTC 9990, NBRC 100380.

Sequence accession no. (16S rRNA gene): AJ252833.

19. **Pseudonocardia nitrificans** (*ex* Schatz, Isenberg, Angrist and Schatz 1954) Warwick, Bowen, McVeigh and Embley 1994, 298[VP] ("*Streptomyces nitrificans*" Schatz, Isenberg, Angrist and Schatz 1954, 2)

ni.tri.fi′cans. N.L. part. adj. *nitrificans* nitrifying.

Produces straight, branched, sporulating aerial hyphae. Grows on various simple and complex agar media. Grows better at 25–30°C than at 37°C. Develops a brick-red mycelium without hemolysis on blood agar, and a gray sporulated surface with a pink to buff reverse on other media; does not produces diffusible pigments. Forms a well sporulating pellicle in nutrient broth and other liquid media. Growth is gnarled and wrinkled on beet, carrot, and potato slants.

Urethane is used as a sole source of carbon, energy, and nitrogen. Produces nitrite from carbamate, but does not oxidize urethane nitrogen beyond nitrite. Slowly alkalinizes milk without curdling. Does not degrade cellulose or produce indole. Ethanol, fumarate, lactate, and *n*-propanol are used as sole carbon sources. Ammonia, guanidine, nitrate, nitrite, purines, urea, and several amino acids are used as sole nitrogen sources. Additional phenotypic features are shown in Table 229.

Source: isolated from soil enriched with urethane as a sole carbon, nitrogen, and energy source.

DNA G+C content (mol%): not determined.

Type strain: IFAM 379.

Sequence accession no. (16S rRNA gene): X55609.

20. **Pseudonocardia oroxyli** Gu, Luo, Zheng, Liu and Huang 2006, 2194[VP]

o.ro.xy′li. N.L. gen. n. *oroxyli* of the plant genus *Oroxylum*.

Forms aerial and substrate hyphae which fragment into smooth rod-shaped elements. Swellings are produced at hyphal tips. The cinnamon-buff substrate mycelium carries pinkish cinnamon aerial hyphae. Grows well on glucose-yeast extract-malt extract agar after 3 d at 25–30°C. Does not produce diffusible pigments.

Acid is produced from galactose, glycerol, mannose, melezitose, and sucrose, but not from dulcitol, inositol, D-lactulose, or D-sorbose. Acetate, L-alanine, L-arabinose, L-arginine, cellobiose, citrate, fructose, galactose, glucose, glutamic acid (weak), glycerol, glycogen, inulin, inositol, lactose, D-lactulose, L-leucine, malate, mannitol, maltose, mannose, melezitose, methyl α-D-glucoside, L-methionine, L-ornithine, oxalate (weak), L-phenylalanine, L-proline, raffinose, rhamnose, ribose, salicin (weak), sorbitol, succinate, sucrose, trehalose, L-valine, and D-xylose are used as sole carbon sources, but not L-arginine, L-cysteine, L-leucinamide, L-tyrosine, or malonate. L-Ornithine is used as a sole nitrogen source, but not L-cysteine, L-threonine, or L-tyrosine. Additional phenotypic features are shown in Table 229.

The predominant fatty acid is $C_{16:0}$ iso (45.1%); smaller amounts of $C_{16:0}$ 10-methyl (11.1%), $C_{17:1}$ ω6*c* (7.4%), iso-H-$C_{16:1}$ (7.1%), $C_{18:1}$ ω9*c* (5.1%), $C_{15:0}$ iso (4.4%), $C_{16:1}$ ω7*c*

(4.3%), $C_{14:0}$ iso (3.5%), and $C_{16:0}$ (3.0%) are also formed. The cellular polar lipid pattern contains phosphatidylethanolamine, phosphatidylinositol, phosphatidylmethylethanolamine, two glucosamine-containing phospholipids of unknown structure, and two glycolipids.

Source: the type strain was isolated from a surface-sterilized root of *Oroxylum indicum* collected in the rain forest around Liusha River, southwest of Jinghong City, Yunnan Province, China.

DNA G+C content (mol%): 70.6 (T_m).

Type strain: strain D10, CGMCC 4.3143, DSM 44984, JCM 13909.

Sequence accession no. (16S rRNA gene): DQ343154.

Further comments: metabolizes a diverse range of carbon compounds on Biolog GP2 and SEP2 microplates, and nitrogen sources on Biolog PM3 plates (Mahendra and Alvarez-Cohen, 2005).

21. **Pseudonocardia petroleophila** (Hirsch and Engel 1956) Warwick, Bowen, McVeigh and Embley 1994, 298[VP] (Basonym: *Nocardia petroleophila* Hirsch and Engel 1956, 445.)

pe.tro.le.oph′il.a. Gr. n. *petra* stone; L. n. *oleum* oil; Gr. adj. *philus* loving; N.L. fem. adj. *petroleophila* loving stone oil, petroleum.

Substrate mycelium is yellowish, citron, or ochre-yellow depending on the carbon or nitrogen source. It fragments into bacillary elements under autotrophic and heterotrophic growth conditions, but much more rapidly in the latter case. Abundant snow-white aerial hyphae, which fragment into spore-like fragments with age, are produced on mineral media. Optimal temperature for growth is 25–28°C; slight growth is evident at 37°C, but does not grow at 50°C. Grows at pH 6.8–8.3. Grows on certain organic media, but without aerial mycelium production and with rapid fragmentation of substrate mycelium. Grows slowly but abundantly on all mineral salts media. Growth rate increases in a petroleum atmosphere. Atmospheric carbon dioxide is used as a carbon and energy source. Does not coagulate or peptonize milk. Grows in the presence of 10% NaCl. Additional phenotypic features are shown in Table 229.

Source: isolated from soil collected in Germany.

DNA G+C content (mol%): not determined.

Type strain: ATCC 15777, CIP 104515, DSM 43193, IFAM 78, IFO (now NRBC) 14406, JCM 3378, JCM 3394, NRRL B-16301, VKM Ac-865.

Sequence accession no. (16S rRNA gene): AJ252828.

22. **Pseudonocardia saturnea** (Hirsch 1960) Warwick, Bowen, McVeigh and Embley 1994, 298[VP] [Basonym: *Nocardia saturnea* Hirsch 1960, 401; *Amycolata saturnea* (Hirsch 1960) Lechevalier, Prauser, Labeda and Ruan 1986, 34.]

sa.tur′ne.a. L. n. *Saturnus* Saturn, Roman god of seed sowing; N.L. fem. adj. *saturnea* pertaining to Saturn, referring to the colonies which have a Saturnian shape.

Yellowish white to bright butter yellow substrate hyphae fragment into rod-shaped elements, especially on organic media. Aerial hyphae are white to yellowish and fragment into long rectangular elements on nutritionally poor media. Grows at 10–37°C (optimum at 28–30°C), but does not grow at 42°C.

CO_2 is used as a sole source of carbon for energy and growth. Positive for catalase, esculin, and phosphatase. Does not degrade casein. Decarboxylates benzoate, lactate, propionate, and pyruvate, but not mucate or tartrate. Acid is produced from inositol, mannose, melezitose, methyl α-D-glucoside, 1,2-propanediol, and sucrose, but not from galactose or xylitol. Additional phenotypic features are shown in Table 229.

The cellular polar lipid pattern contains phosphatidycholine and phosphatidylmethylethanolamine, but not phosphatidylethanolamine. The predominant menaquinones are MK-8(H_2) and MK-8(H_4).

Source: isolated from air and compost in Germany.

DNA G+C content (mol%): 72 (T_m).

Type strain: ATCC 15809, DSM 43195, IFO (now NRBC) 14499, IMRU 1181, JCM 3187, NRRL B-16172, VKM Ac-781.

Sequence accession no. (16S rRNA gene): AJ252829.

23. **Pseudonocardia spinosa** Schäfer *in* Henssen and Schäfer 1971, 31[AL]

spi.no′sa. L. fem. adj. *spinosa* spiny.

Substrate hyphae are compact, irregularly branched, constricted, and septate; swellings are common. Aerial hyphae are constricted or septate. Spores are formed on substrate and aerial mycelia either by budding or secondary septation of hyphal segments. Inner wall layers of hyphae and spores vary in thickness. Grows extremely slowly. Moderate to good growth occurs on oatmeal and yeast-starch agars. Yellow colonies covered by abundant white aerial mycelium are formed on asparagine-glycerol agar. Optimal temperature for growth is between 20 and 30°C. Additional phenotypic features are shown in Table 229.

Source: isolated from soil collected in Turkey.

DNA G+C content (mol%): not determined.

Type strain: strain MB SH-1, ATCC 25924, CBS 818.70, IFO (now NRBC) 16002, JCM 3136.

Sequence accession no. (16S rRNA gene): not determined.

24. **Pseudonocardia spinosispora** Lee, Kim, Kang and Hah 2002, 1607[VP]

spi.no.si.spo′ra. L. adj. *spinosus* thorny; Gr. fem. n. *spora* seed; N.L. fem. n. *spora* spore; N.L. fem. n. *spinosispora* thorny spore.

Substrate hyphae are sparse or absent on most cultivation media; the reverse color is deep brown in older cultures. A well developed white aerial mycelium fragments into rod-shaped elements (approx. 0.54 × 2.25 μm), which are covered with numerous spines. Growth occurs in standing, but not in shaken, cultures. Grows at temperatures between 4 and 30°C.

Produces H_2S, but does not degrade casein, gelatin, or starch. Acid is produced from glycerol, inositol, mannose, and D-xylitol, but not from 2,3-butanediol, dulcitol, galactose, melezitose, melibiose, methyl α-D-glucoside, methyl α-D-mannoside, 1,2-propanediol, raffinose, sorbose, or sucrose. Additional phenotypic features are shown in Table 229.

The major fatty acids contain $C_{16:0}$ iso (33.8%), $C_{15:0}$ iso (13.8%), $C_{17:0}$ iso (10.0%), $C_{17:1}$ (9.5%), $C_{16:1}$ iso (7.4%), $C_{17:1}$ iso (7.2%), and $C_{16:1}$ iso (6.0%); also contains small amounts of 10-methyl-branched fatty acids, but not tuber-

culostearic acid or hydroxy fatty acids. The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, phosphatidylmethylethanolamine, hydroxyphosphatidylethanolamine, and an unknown phospholipid.

Source: isolated from soil from a gold mine cave near Kongju City, Korea.

DNA G+C content (mol%): 70.4 (HPLC).

Type strain: strain LM 141, IMSNU 50581, KCTC 9991, NRRL B-24156.

Sequence accession no. (16S rRNA gene): AJ249206.

25. **Pseudonocardia sulfidoxydans** Reichert, Lipski, Pradella, Stackebrandt and Altendorf 1998, 448[VP]

sul.fi.do′xy.dans. N.L. n. *sulfidum* sulfide; N.L. part. adj. *oxydans* oxidizing; N.L. part. adj. *sulfidoxydans* oxidizing sulfides.

Aerial and substrate mycelia fragment into rod-shaped elements. Hyphal segments are sometimes swollen up to 5 µm. Shows zig-zag mycelial growth and longitudinal and transverse hyphal septa. Yellow substrate hyphae and white aerial hyphae, which carry long chains of oval spores, are formed on trypticase soy agar.

Acid is produced from galactose, glycerol, mannose, and sucrose, but not from dulcitol, inositol, D-lactulose, melezitose, methyl α-D-glucoside, D-sorbose, or raffinose. L-Aniline-*p*NA, *o*NP-β-D-galactopyranoside, *p*NP-α-D-glucopyranoside, *bis*-*p*NP-phosphate, *p*NP-phenyl-phosphate, and L-proline-*p*NA are hydrolyzed, but not 2-deoxythymidine-5′-*p*NP-phosphate, esculin, *p*NP-β-D-glucopyranoside, L-glutamate-γ-3-carboxy-*p*NA, or *p*NP-phosphorylcholine. Dimethyl disulfide and dimethyl sulfide are oxidized. Grows on 4-hydroxybutyrate and 4-aminobutyrate (10 mM each). Additional phenotypic features are shown in Table 229.

The major fatty acids are $C_{16:0}$ iso (24.8–32.3%), $C_{16:0}$ (15.0–30.5%), and $C_{15:0}$ iso (11.2–16.4%). Mycolic acids are not formed. The cellular polar lipid pattern contains diphosphatidylglycerol, hydroxyphosphatidylethanolamine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, phosphatidylmethylethanolamine, and a ninhydrin-positive component.

Source: isolated from tree-bark compost biofilters from an animal-rendering plant.

DNA G+C content (mol%): not determined.

Type strain: strain 592, CIP 105686, DSM 44248, IFO (now NRBC) 16205, JCM 10411.

Sequence accession no. (16S rRNA gene): Y08537.

Further comments: metabolizes a diverse range of substrates on Biolog GP2 and SFP2 microplates and nitrogen sources on Biolog PM3 plates (Mahendra and Alvarez-Cohen, 2005).

26. **Pseudonocardia tetrahydrofuranoxydans** Kämpfer, Kohlweyer, Thiemer and Andreesen 2006, 1536[VP]

te.tra.hy.dro.fu.ra.no′xy.dans. N.L. n. *tetrahydrofuranum* tetrahydrofuran; N.L. v. *oxydare* to make acid, to oxidize; N.L. part. adj. *tetrahydrofuranoxydans* oxidizing tetrahydrofuran.

Forms branched filaments (e.g. 1.3 µm in width) that produce cell aggregates in THF-containing medium. Single spore-like bodies are formed at the end of cells. Aerial mycelium on agar is white, branched, and becomes fragmented. Good growth occurs on nutrient and R3A agars after 3 d at 25–30°C. Growth on THF occurs between 11 and 36°C.

L-Aniline-*p*NA and L-proline-*p*NA are hydrolyzed, but not 2-deoxythymidine-5′-*p*NP-phosphate, esculin, *o*NP-β-D-galactopyranoside, *p*NP-β-D-glucuronide, *p*NP-α-glucopyranoside, *p*NP-β-D-glucopyranoside, L-glutamate-γ-3-carboxyl-*p*NA, *bis-p*NP-phosphate, *p*NP-phenylphosphonate, *p*NP-phosphorylcholine, or *p*NP-α-D-xylopyranoside. Grows on 4-aminobutyrate, 1,4-butanediol, 2,4-diaminobutyrate, 4-hydroxybutyrate, DL-3-hydroxybutyrate, and some purines and ethers, but not on 4-aminobutyrate, chlorinated benzenes, dimethylsulfide, or hydrocarbons (C6 or petroleum). Additional phenotypic features are shown in Table 229.

Major fatty acids are $C_{16:0}$ iso (24.8–32.3%), $C_{15:0}$ iso (11.2–16.4%), and $C_{16:0}$ (15.0–30.5%); small to moderate amounts of methyl-branched fatty acids are also present.

Source: the type strain was isolated from an enrichment culture containing THF as the sole source of carbon, and originated from sludge of a wastewater treatment plant in Göttingen, Germany.

DNA G+C content (mol%): 71.3 (HPLC).

Type strain: strain K1, CIP 109050, CCUG 52126, DSM 44239, JCM 14745.

Sequence accession no. (16S rRNA gene): AJ249200.

Further comments: metabolizes a broad range of carbon compounds on Biolog GP2 plates (Kämpfer et al., 2006).

27. **Pseudonocardia xinjiangensis** (Xu, Jin, Mao, Lu, Cui and Jiang 1999) Huang, Wang, Lu, Hong, Liu, Tan and Goodfellow 2002, 981[VP] (Basonym: *Actinobispora xinjiangensis* Xu, Jin, Mao, Lu, Cui and Jiang 1999, 885.)

xin.ji.ang.en′sis. N.L. fem. adj. *xinjiangensis* pertaining to Xinjiang, an autonomous region in northwest China.

Forms substrate and aerial hyphae that are branched, but do not fragment. Spores are borne in longitudinal pairs on vegetative hyphae and either singly or in longitudinal pairs on aerial hyphae. An orange-yellowish substrate mycelium carries sparse, white aerial hyphae. Neither diffusible nor melanin pigments are produced. Does not grow at 45°C. Does not degrade cellulose, pectin, or starch, produce lecithinase or H_2S, or reduce nitrate. Adonitol, cellobiose, fructose, inositol, inulin, mannitol, raffinose, and xylose are used as sole carbon sources. Acid is not produced from these carbon sources. Alanine, L-histidine, and proline are used as nitrogen sources. Additional phenotypic features are shown in Table 229.

The cellular polar lipid pattern contains phosphatidycholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and glucosamine-containing phospholipids.

Source: the type strain was isolated from a soil sample collected from Tolufan, Xinjiang Province, China.

DNA G+C content (mol%): 72.1 (T_m).

Type strain: strain XJ-45, CCTCC AA 97020, CGMCC 4.1538, DSM 44661, JCM 11839.

Sequence accession no. (16S rRNA gene): EU722520.

28. **Pseudonocardia yunnanensis** (Jiang, Xu, Yang, Guo, Ma and Liu 1991) Huang, Wang, Lu, Hong, Liu, Tan and Goodfellow 2002, 981[VP] (Basonym: *Actinobispora yunnanensis* Jiang, Xu, Yang, Guo, Ma and Liu 1991, 527)

yun.nan.en′sis. N.L. fem. adj. *yunnanensis* pertaining to Yunnan, a province of south China.

Substrate and aerial hyphae are branched and do not fragment. A yellow substrate mycelium carries sparse, white aerial hyphae. Spores are borne in longitudinal pairs on vegetative hyphae and either singly or in longitudinal pairs on aerial hyphae. Neither diffusible nor melanin pigments are produced. Grows at 45°C. Does not degrade cellulose, gelatin, starch, or pectin. Milk is coagulated and peptonized. Nitrate is not reduced; lecithinase and H_2S are not produced. Adonitol, cellobiose, fructose, inositol, mannitol, raffinose, and xylose are used as sole carbon sources.

Susceptible to neomycin and rifampin (each at 50 µg/ml). Additional phenotypic features are shown in Table 229.

The cellular polar lipid pattern contains phosphatidylethanolamine, phosphatidylmethylethanolamine, and glucosamine-containing phospholipids

Source: isolated from a soil sample collected in Weixin, Yunnan Province, China.

DNA G+C content (mol%): 73.4 (T_m).

Type strain: strain Y-11981, CCTCC M 90959, CGMCC 4.1542, DSM 44253, NBRC 15681, JCM 9330, VKM Ac-1991.

Sequence accession no. (16S rRNA gene): AJ252822.

29. **Pseudonocardia zijingensis** Huang, Wang, Lu, Hong, Liu, Tan and Goodfellow 2002, 981[VP]

zi.jing.en′sis. N.L. fem. adj. *zijingensis* pertaining to Zijing, the source of the soil from which the organism was isolated.

The aerial and substrate mycelia fragment into rod-shaped elements. Chains of smooth spores are produced by acropetal budding on the substrate mycelium. Branched yellow substrate hyphae and white aerial hyphae are formed on trypticase soy broth agar. Does not produce diffusible pigments. Growth occurs at 15–45°C. Produces lipase. Additional phenotypic features are shown in Table 229.

The cellular polar lipid pattern contains diphosphatidylglycerol, phosphatidycholine, phosphatidylglycerol, phosphatidylinositolmannosides, and phosphatidylmethylethanolamine, but not glucosamine-containing phospholipids.

Source: isolated from a soil sample of Zijing Mountain, Yunnan Province, China.

DNA G+C content (mol%): 70.9 (T_m).

Type strain: strain 6330, CGMCC 4.1545, DSM 44774, JCM 11117.

Sequence accession no. (16S rRNA gene): AF325725.

Genus II. **Actinoalloteichus** Tamura, Zhiheng, Yamei and Hatano 2000, 1439[VP]

Tomohiko Tamura

Ac.ti.no.al.lo.tei′chus. Gr. n. *actis*, *actinos* ray (used to refer to actinomycetes); Gr. adj. *allos* another, the other; Gr. masc. n. *teichos* wall; N.L. masc. n. *Actinoalloteichus* actinomycete with a different wall.

Stains Gram-positive, not-acid-fast. A fine, non-fragmenting, branching mycelium is produced. Strictly aerobic. Non-fragmentary substrate mycelia are present. Aerial mycelia are formed with an **aggregate of straight spore chains**. The aerial and substrate mycelia tend to fragment. Good growth occurs at 20–37°C. The organism shows good growth on yeast extract-malt extract agar and oatmeal agar. Cell walls contain glutamate, glucosamine, alanine, and *meso*-diaminopimelate. $C_{17:0}$ anteiso, $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{15:0}$ anteiso are the major cellular fatty acids present. The major menaquinone is MK-9(H_4); small amounts of MK-8(H_4) and MK-9(H_2) are also present. Phosphatidylethanolamine and phosphatidylmonomethylethanolamine are present as diagnostic phospholipids. The acyl type of the cell wall is acetyl.

DNA G+C content (mol%): 72–73.

Type species: **Actinoalloteichus cyanogriseus** Tamura, Zhiheng, Yamei and Hatano 2000, 1439[VP].

Further descriptive information

Ribose, mannose, galactose, and glucose are detected in whole-cell sugars, but arabinose is not. The wall corresponds to chemotype III according to Lechevalier and Lechevalier (1970). The fatty acid and menaquinone compositions of the species of *Actinoalloteichus* are given in Table 230. *Actinoalloteichus hymeniacidonis* can be distinguished from the other species of the genus by its higher concentrations of $C_{17:1}$ ω8*c*, $C_{17:0}$, and $C_{15:0}$ anteiso. Species of *Actinoalloteichus* grow well on a variety of sugars. Other physiological characteristics are summarized in Table 231.

Enrichment and isolation procedures

The type strain of *Actinoalloteichus cyanogriseus* was isolated from a soil sample collected from Yunnan, China (Liu et al., 1984). The type strain of *Actinoalloteichus hymeniacidonis* was isolated

from a marine sponge collected at the inter-tidal beach of Dalian, on the Chinese Yellow Sea, located in northern China. Freshly collected sponge specimens were rinsed five times in sterile seawater to remove transient and loosely attached bacteria and then thoroughly homogenized in a sterile mortar. A 10-fold dilution series of sponge homogenate was plated in triplicate on modified arginine-glycerol agar (ISP medium 5) plates, consisting of glycerol (0.6%, v/v), arginine (0.1%, w/v), K_2HPO_4 (0.1%, w/v), $MgSO_4$ (0.05%, w/v), and agar (1.8%, w/v) in natural seawater. The type strain of *Actinoalloteichus spitiensis* was isolated from a soil sample collected from the Lahaul–Spiti Valley, a cold desert of the Indian Himalayas, by using a dilution plating technique on actinomycetes isolation agar, containing (in w/v): sodium caseinate (0.2%), asparagine (0.01%), sodium propionate (0.4%), dipotassium phosphate (0.05%), magnesium sulfate (0.01%), ferrous sulfate (0.0001%), and agar (1.5%), pH 8.1. Incubation was at 28°C for 2 to 4 weeks.

Maintenance procedures

Strains of the genus *Actinoalloteichus* are maintained by freezing in water containing 10–30% glycerol at −70°C. Lyophilization of suspensions in 10% skim milk+1% monosodium glutamate and L-drying in 0.01 M potassium phosphate buffer (pH 7.0) containing 3% monosodium glutamate (Sakane and Kuroshima, 1997) are also recommended for long-term preservation.

Differentiation of the genus *Actinoalloteichus* from other genera

The genus *Actinoalloteichus* develops aerial mycelium with straight chains of spores, contains galactose as the characteristic whole-cell sugar, and *meso*-diaminopimelate, glutamate, and alanine as the cell-wall amino acids. Phylogenetic analysis indicates that the genus *Actinoalloteichus* is closely related to the genera *Goodfellowiella* (Labeda and Kroppenstedt, 2006) and *Streptoalloteichus* (Tomita et al., 1987). The genus *Goodfellowiella* has $C_{17:0}$ 10-methyl and anteiso-branched 2-hydroxy fatty acids. *Streptoalloteichus* develops motile spores in sporangia. On the other hand, the genus *Actinoalloteichus* lacks 10-methyl fatty acids and does not develop sporangia or motile cells. The genera *Saccharothrix* (Labeda et al., 1984), *Actinosynnema* (Hasegawa et al., 1978), and *Thermocrispum* (Korn-Wendisch et al., 1995) have *meso*-diaminopimelic acid in the cell wall (cell-wall type III) and long chains of spores. However, the genus *Actinoalloteichus* can be distinguished from these genera by its morphological characteristics, fatty acid components, and the absence of motility.

Taxonomic comments

The species *Streptomyces caeruleus* has been reclassified as *Actinoalloteichus cyanogriseus* based on 16S rRNA gene sequence analysis and DNA hybridization (Tamura et al., 2008a). The genus *Actinoalloteichus* belongs to the family *Pseudonocardiaceae* of the order *Pseudonocardiales*.

Differentiation of the species of the genus *Actinoalloteichus*

Characteristics of the three *Actinoalloteichus* species are given in Table 230 and Table 231.

List of species of the genus *Actinoalloteichus*

1. **Actinoalloteichus cyanogriseus** Tamura, Zhiheng, Yamei and Hatano 2000, 1439[VP]

cya.no.gri′se.us. L. adj. *cyaneus* deep blue; N.L. adj. *griseus* gray; N.L. masc. adj. *cyanogriseus* blue-gray.

The vegetative mycelia are brown to gray in color and the aerial mycelia are blue to gray. A black soluble pigment is produced on yeast extract-malt extract agar. Decomposition of urea, growth in Sabouraud glucose broth and MacConkey agar, hydrolysis of esculin and hippurate, utilization of sodium citrate, sodium succinate and calcium malate, gelatin liquefaction and reduction of nitrate are all negative. Glucose, maltose, xylose, mannitol, rhamnose, mannose, and sorbitol are utilized, but inositol, fructose, and raffinose are not. No growth at 15 or 45°C.

Source: the type strain was isolated from cultivated soil.

DNA G+C content (mol%): 73 (HPLC).

Type strain: AS 4.1159, CIP 106755, DSM 43889, NBRC 14455, JCM 6095, NRRL B-16252.

Sequence accession no. (16S rRNA gene): AB006178.

2. **Actinoalloteichus hymeniacidonis** Zhang, Zheng, Huang, Luo, Jin, Zhang, Liu and Huang 2006, 2311[VP]

hy.me.ni.a.ci′do.nis. N.L. gen. n. *hymeniacidonis* of *Hymeniacidon*, the generic name of the marine sponge *Hymeniacidon perleve*, the source of the type strain.

Aerial mycelia are produced with aggregates of straight chains of spores (0.6–0.8 µm). Grows well on yeast extract-malt extract agar and oatmeal agar at 20–37°C. A black soluble pigment is produced on yeast extract-malt extract agar and peptone-yeast extract-iron agar. Decomposition of urea, growth in Sabouraud glucose broth and MacConkey agar, hydrolysis of esculin and hippurate, utilization of calcium malate, sodium oxalate and sodium succinate, and reduction of nitrate are all negative. Fructose, glucose, maltose, mannose, mannitol, rhamnose, sucrose, sorbitol, and xylose are utilized as sole carbon sources, but arabinose, inositol, and raffinose are not. Grows weakly at 15°C and does not grow at 45°C. The cell-wall chemotype is III. The major menaquinone is MK-9(H_4); small amounts of MK-9(H_6) and MK-9(H_8) are also present. The phospholipid profile comprises mainly phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannoside. Major cellular fatty acids are $C_{15:0}$ anteiso (20%), $C_{17:1}$ ω8*c* (19%), $C_{16:0}$ iso (16%), and $C_{17:0}$ (11%).

Source: the type strain was isolated from a marine sponge, *Hymeniacidon perleve*, in Dalian, China (type strain).

DNA G+C content (mol%): not reported.

Type strain: HPA177, CGMCC 4.2500, JCM 13436.

Sequence accession no. (16S rRNA gene): DQ144222.

3. **Actinoalloteichus spitiensis** Singla, Mayilraj, Kudo, Krishnamurthi, Prasad and Vohra 2005, 2563[VP]

spi.ti.en′sis. N.L. masc. adj. *spitiensis* pertaining to Spiti Valley, located in the Indian Himalayas, where the type strain was isolated.

No aerial mycelium or spores are produced. Positive for utilization of D-mannitol, raffinose, sucrose, salicin, sodium citrate, and sodium succinate as sole carbon sources. Negative for utilization of D-glucose, maltose, *myo*-inositol, D-fructose, D-arabinose, D-xylose, L-rhamnose, D-mannose, and D-sorbitol as sole carbon sources. Positive for decomposition of casein and negative for decomposition of urea. No growth occurs on MacConkey agar or in Sabouraud glucose broth. Positive for hydrolysis of starch and negative for hydrolysis of hippurate and esculin. Tolerates up to 2% NaCl. Grows at temperatures between 20 and 37°C, with an optimum temperature of 25°C; it cannot grow at 15 or 42°C. Growth occurs at initial pH values between 6 and 11, the optimum being pH 8.0. Major fatty acids are $C_{16:0}$ iso (33.0%) and $C_{15:0}$ iso (17.0%), with lesser amounts of $C_{15:0}$ anteiso (7.0%) and $C_{17:0}$ anteiso (8.0%). The major menaquinone is MK-9(H_4) (82%). MK-9(H_2) is absent.

Source: the type strain was isolated from soil 3600 m above sea level, at Rangrik Village in Spiti Valley, Himachal Pradesh, India.

DNA G+C content (mol%): 72 (HPLC).

Type strain: RMV-1378, DSM 44848, JCM 12472, MTCC 6194.

Sequence accession no. (16S rRNA gene): AY426714.

Genus III. **Actinokineospora** Hasegawa 1988a, 449[VP] (Effective publication: Hasegawa 1988b, 33.)

David P. Labeda

Ac.ti.no.ki.ne.o.spo′ra. Gr. n. *aktis -inos* ray; Gr. v. *kineo* to set in motion; Gr. fem. n. *spora* seed and in biology a spore; N.L. fem. n. *Actinokineospora* actinomycete bearing zoospores.

Forms hyphae (approx. 0.5 µm in diameter) that differentiate into a vegetative mycelium that penetrates the agar medium and forms colonies on the surface; aerial mycelium arises from the colony. **Aerial hyphae bear chains of conidia capable of forming flagella in an aqueous environment.** Gram-stain-positive. Catalase-positive. Aerobic. **The cell wall contains *meso*-diaminopimelic acid as the diamino acid along with glycine, D-glutamic acid, and L-alanine, properties characteristic of type A1γ peptidoglycan. The characteristic whole-cell sugars are arabinose and galactose, but very little arabinose is found in purified cell walls. The phospholipid pattern consists of significant amounts of phosphatidylethanolamine along with diphosphatidylglycerol and phosphatidylinositol. The principal menaquinone is MK-9(H_4).** Phylogenetically, within the the order *Pseudonocardiales* based on 16S rRNA gene sequences.

DNA G+C content (mol%): 72.0 (T_m).

Type species: **Actinokineospora riparia** Hasegawa 1988a, 449[VP] (Effective publication: Hasegawa 1988b, 33.).

Further descriptive information

The genus *Actinokineospora* was described by Hasegawa (1988b, 1988a) for a novel actinomycete strain isolated from a soil sample collected on the side of the Ado River in Shiga Prefecture, Japan. This strain was unique in that it produced motile zoospores (Figure 285) from aerial hyphae (Figure 286) and was found to have both arabinose and galactose as diagnostic sugars in whole-cell hydrolysates, thereby distinguishing it from all described actinomycete genera. Subsequently, members of an additional six species of this genus that exhibited similar morphology and chemotaxonomy were isolated and described. Phylogenetic analysis of *Actinokineospora* species based on 16S rRNA gene sequences places the genus within the suborder *Pseudonocardineae* (Figure 287), elevated to the order *Pseudonocardiales* in this volume, along with other genera which produce motile zoospores, such as *Actinosynnema* and *Streptoalloteichus*, but members of these taxa produce structures such as synnemata and sporangia, respectively, which are not present in *Actinokineospora*. All *Actinokineospora* species described to date have been found associated with plant leaves and soil samples.

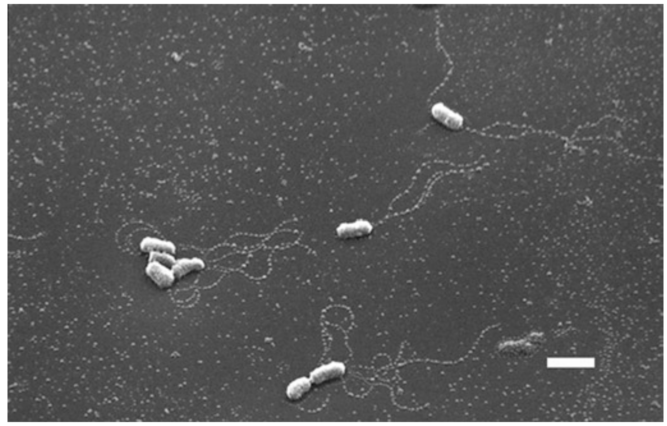

FIGURE 286. Electron micrograph of zoospores of *Actinokineospora enzanensis* NBRC 16517^T. Bar = 1.0 µm. (Electron micrograph courtesy of Misa Otogura, NBRC, Japan.)

Enrichment and isolation procedures

Strains of *Actinokineospora* have been routinely isolated on humic acid-vitamin agar (HV agar; Hayakawa and Nonomura, 1987), using a modification of the procedure of Makkar and Cross (1982). Soil or leaf litter samples are air-dried at 28°C for 7 d, 0.5 g sample is mixed with 50 ml sterile tap water, and the mixture is incubated at 20°C for 55 min with occasional shaking. Aliquots (0.1 ml) of dilutions of the supernatant are spread on the surface of plates and incubated at 28°C for 2–3 weeks.

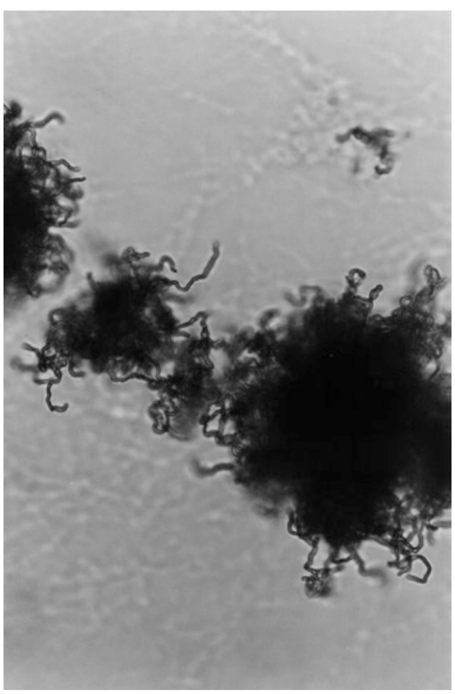

FIGURE 285. Light micrograph of the aerial mycelium on a culture of *Actinokineospora riparia* on sucrose-nitrate agar.

Hayakawa et al. (2000) described an isolation method for strains of *Actinokineospora* and other actinomycetes that have motile zoospores from soils and plant material. They placed a 0.5 g sample of air-dried soil or leaf litter in a beaker and gently flooded it with 50 ml sterile 10 mM phosphate buffer (pH 7.0) containing 10% soil extract. After incubating the sample for 90 min at 30°C, the motile zoospores that might be present are released. Following low speed (i.e. 1500 × *g*) centrifugation for 20 min and a subsequent 30 min incubation period, the samples were serially diluted and 200 µl aliquots plated onto an appropriate isolation medium, such as HV medium (Hayakawa and Nonomura, 1987) containing 50 µg/ml cycloheximide and with/without trimethoprim (20 µg/ml) and nalidixic acid (10 µg/ml). After a 2–3 week incubation period at 30°C, the plates are observed using a microscope fitted with a long working distance objective for the tentative identification of putative *Actinokineospora* strains based on morphological criteria.

Maintenance procedures

Working cultures of *Actinokineospora* can be maintained as refrigerated (4°C) agar slants on an appropriate medium such as NZamine medium (DSMZ medium 554; DSMZ, 2001). The slants are generally incubated for 5–7 d at 28–30°C prior to refrigeration and then should be subcultured at monthly intervals. Long-term preservation of strains is best accomplished as frozen stocks in 20% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques.

Procedures for testing special characters

Strains are routinely cultivated on NZamine medium (DSMZ medium 554) at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and NZamine medium.

Chemotaxonomic analysis of strains for fatty acids, menaquinones, and polar lipids are performed using methods described previously by Grund and Kroppenstedt (1989), Minnikin et al. (1984), Saddler et al. (1991), and Sasser (1990).

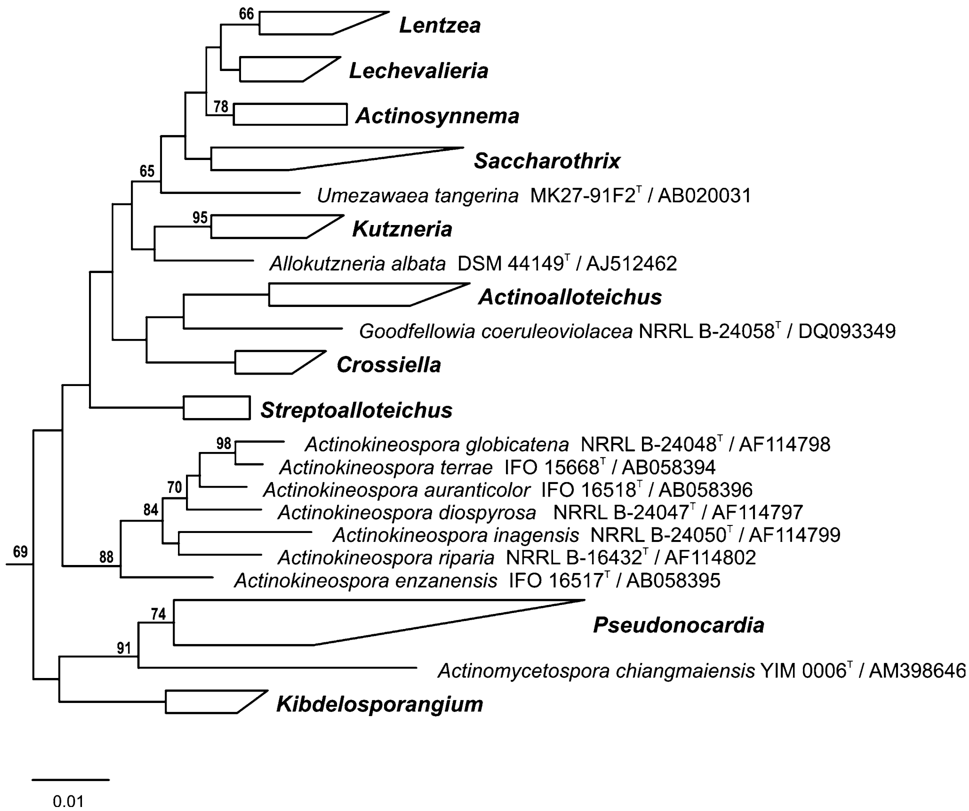

FIGURE 287. Phylogenetic tree for the genus *Actinokineospora* and related genera within the suborder *Pseudonocardineae* (now the order *Pseudonocardiales*) calculated from almost-complete 16S rRNA gene sequences using the Kimura's evolutionary distance method (Kimura, 1980) and the neighbor-joining algorithm of Saitou and Nei (1987). Numbers at the nodes represent levels of bootstrap support (%; Felsenstein, 1989) from 100 resampled datasets; values less than 60% are not shown. Bar = 0.01 nucleotide substitutions per site.

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, guanine, hippurate, hypoxanthine, tyrosine, xanthine, and urea are typically determined using the media of Gordon et al. (1974). Phosphatase activity is evaluated by using the method of Kurup and Schmitt (1973) substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of NZamine medium and salt tolerance on slants of the same medium supplemented with 4 and 5% (w/v) NaCl.

Differentiation of the genus *Actinokineospora* from other genera

Actinokineospora strains can be easily differentiated from other genera morphologically based on their production of motile zoospores from aerial mycelia in the absence of elaborate structures such as sporangia or synnemata. They are chemotaxonomically distinct from other related actinomycete genera producing motile zoospores in the presence of arabinose in the whole-cell sugar hydrolysate pattern (Table 232) and are phylogenetically distinct based on 16S rRNA gene sequences (Figure 287).

Differentiation of the species of the genus *Actinokineospora*

The physiological characteristics of *Actinokineospora* species are summarized in Table 233 and can be used to differentiate between species, although a common set of physiological tests has not been used in the description of all species. Gross colonial morphology provides some additional information of the species based on the color of the substrate mycelium, production and color of aerial mycelium, and on the formation and color of soluble pigments when growing on agar media.

TABLE 232. Chemotaxonomic profiles of *Actinokineospora* and phylogenetically closely related genera

[b]All species hydrolyzed hippurate but not xylan. None grew on erythritol, inositol, D-lactose, mannitol, raffinose, sorbitol, or xylose as sole carbon sources or in the presence of 0.2% *p*-hydroxybenzaldehyde or 0.1% phenylethanol. All species grew at 25°C and 30°C and were resistant to bekanamycin (20 and 40 µg/ml), kanamycin (40 and 80 µg/ml), oxytetracycline (20 µg/ml), and vancomycin (0.25 µg/ml).

List of species of the genus *Actinokineospora*

1. **Actinokineospora riparia** Hasegawa 1988a, 449[VP] (Effective publication: Hasegawa 1988b, 33.)

ri.pa′ri.a. L. fem. adj. *riparia* that frequents the banks of rivers, riverside, referring to the collection site of the soil sample from which the type strain was isolated, along the Ado River, Japan.

Vegetative mycelium varies in color from colorless on most media to yellowish-white on some media and tan to brown on yeast extract-malt extract agar. Aerial mycelium is white in color when produced. Tyrosine is decomposed, but not adenine, hypoxanthine, or xanthine. Growth is observed on D-glucose, soluble starch, and trehalose, with weak growth on cellulose, inulin, and melibiose; does not grow on adonitol, erythritol, ribose, salicin, L-sorbose, or dulcitol. Temperature for growth is 28°C.

Source: isolated from a soil sample collected on the side of the Ado River, Shiga Prefecture, Japan.

DNA G+C content (mol%): 72 (T_m).

Type strain: C-39162, ATCC 49499, DSM 44259, NBRC 14541, JCM 7471, NRRL B-16432, VKM Ac-1980.

Sequence accession no. (16S rRNA gene): AF114802.

2. **Actinokineospora auranticolor** Otoguro, Hayakawa, Yamazaki, Tamura, Hatano and Iimura 2003, 1[VP] (Effective publication: Otoguro, Hayakawa, Yamazaki, Tamura, Hatano and Iimura 2001, 38.)

au.ran.ti.co′lor. N.L. n. *Aurantium* generic name of the orange; L. n. *color* tint, hue; N.L. adj. *auranticolor* orange colored.

Yellowish-orange substrate mycelium. Aerial mycelium is white to gray. Temperature for growth is 28°C.

Source: isolated from leaves and soil.

DNA G+C content (mol%): 71.3 (HPLC).

Type strain: YU 961-1, DSM 44650, NBRC 16518, JCM 11646.

Sequence accession no. (16S rRNA gene): AB058396.

3. **Actinokineospora diospyrosa** Tamura, Hayakawa, Nonomura, Yokota and Hatano 1995, 378[VP]

di.o.spy′ro.sa. N.L. fem. adj. *diospyrosa* pertaining to the fruit tree *Diospyros kaki*.

Tan substrate mycelium. Aerial mycelia are white to gray. Temperature for growth is 28°C.

Source: isolated from fallen leaves of the persimmon tree, *Diospyros kaki*.

DNA G+C content (mol%): 69.3 (HPLC).

Type strain: YU8-1, DSM 44255, NBRC 15665, JCM 9921, NRRL B-24047, VKM Ac-1984.

Sequence accession no. (16S rRNA gene): AF114797.

4. **Actinokineospora enzanensis** Otoguro, Hayakawa, Yamazaki, Tamura, Hatano and Iimura 2003, 1[VP] (Effective publication: Otoguro, Hayakawa, Yamazaki, Tamura, Hatano and Iimura 2001, 38.)

en.za.nen′sis. N.L. fem. adj. *enzanensis* pertaining to Enzan City, Yamanashi, Japan, where the organism was isolated.

Vegetative mycelium is greenish-gray. Aerial mycelium is sparse and white, when formed. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 70.0 (HPLC).

Type strain: YU 924-101, DSM 44649, NBRC 16517, JCM 11647.

Sequence accession no. (16S rRNA gene): AB058395.

5. **Actinokineospora globicatena** Tamura, Hayakawa, Nonomura, Yokota and Hatano 1995, 377[VP]

glo.bi.ca.te′na. L. n. *globus* a ball, sphere; L. n. *catena* chain; N.L. n. *globicatena* ball of chains, referring to the mass of spore chains that aggregate into balls.

Vegetative mycelium is yellow to golden brown. Aerial mycelium is white to gray. Temperature for growth is 28°C.

Source: isolated from soil and fallen leaves.

DNA G+C content (mol%): 69.5–69.8 (HPLC).

Type strain: YU6-1, DSM 44256, NBRC 15664, JCM 9922, NRRL B-24048, VKM Ac-1981.

Sequence accession no. (16S rRNA gene): AF114798.

6. **Actinokineospora inagensis** Tamura, Hayakawa, Nonomura, Yokota and Hatano 1995, 377[VP]

in.ag.en′sis. N.L. fem. adj. *inagensis* pertaining to Lake Inaga, the lake from which the organism was first isolated.

Yellow to tan substrate mycelium is produced. Aerial mycelium is white to gray in color. Temperature for growth is 28°C.

Source: isolated from fallen leaves.

DNA G+C content (mol%): 69.1 (HPLC).

Type strain: YU4-1, DSM 44258, NBRC 15663, JCM 9923, NRRL B-24050, VKM Ac-1982.

Sequence accession no. (16S rRNA gene): AF114799.

7. **Actinokineospora terrae** Tamura, Hayakawa, Nonomura, Yokota and Hatano 1995, 377[VP]

ter′ra.e. L. gen. n. *terrae* of the earth.

Yellow to golden brown substrate mycelium is produced. Aerial mycelium is white to gray. Temperature for growth is 28°C.

Source: isolated from soil and fallen leaves.

DNA G+C content (mol%): 70.0 (HPLC).

Type strain: YU6-3, DSM 44260, NBRC 15668, JCM 9924, NRRL B-24049, VKM Ac-1983.

Sequence accession no. (16S rRNA gene): AB058394.

Genus IV. **Actinosynnema** Hasegawa, Lechevalier and Lechevalier 1978, 305[AL]

DAVID P. LABEDA

Ac.ti.no.syn′ne.ma. Gr. n. *actis*, *actinos* ray; Gr. adv. *syn* together; Gr. n. *nema*, *nematos* thread; N.Gr. n. *synnema*, threads wrapping together, synnema; N.L. neut. n. *Actinosynnema* indicates a synnema-forming actinomycete.

Fine hyphae (about 0.5 μm in diameter) are **differentiated into substrate mycelium**, with long branching hyphae that penetrate the agar and also grow into and **form synnemata, dome-like bodies, or flat colonies on the agar surface, and aerial hyphae** (0.5–1.0 μm in diameter) **that arise from synnemata, dome-like bodies, or flat colonies. The aerial hyphae bear chains of spores capable of forming flagella in an aqueous environment. The cell walls contain major amounts of *meso*-diaminopimelic acid** (***meso*-DAP**), glutamic acid, alanine, glucosamine, and muramic acid. **The whole-cell sugar pattern consists of galactose and mannose. Principal phospholipids include phosphatidylethanolamine, phosphatidylethanolamine containing 2-hydroxy fatty acids, and diphosphatidylglycerol. Menaquinones are predominantly MK-9(H_4), with some MK-9(H_6)**. Gram-stain-positive. Non acid-fast. Catalase-positive. Aerobic. Mesophilic. Most strains isolated directly from plant tissue. Phylogenetically nearest neighbors are the genera *Lechevalieria* and *Lentzea*.

DNA G+C content (mol%): 71–73 (T_m).

Type species: **Actinosynnema mirum** Hasegawa, Lechevalier and Lechevalier 1978, 305[AL].

Further descriptive information

The genus *Actinosynnema* was described by Hasegawa et al. (1978) to accommodate actinomycetes that produce unique morphological structures called synnemata (Figure 288) or dome-like bodies on most media. Aerial mycelia are produced on these synnemata or dome-like bodies and are initially whitish in color and become yellow to yellowish-orange in color. Regular septation occurs in mature aerial hyphae making it look bamboo-like when observed microscopically and then the hyphae become chains of spores. Suspension of the aerial mycelia in liquid media under a coverslip permits the observation of peritrichously motile zoospores (Figure 289) within 30 min to 1 h.

Phylogenetic analyses based on 16S rRNA gene sequencing demonstrates that the genus *Actinosynnema* is related to the genera *Lechevalieria*, *Lentzea*, and *Saccharothrix*, being intermediate between the first two genera and *Saccharothrix* (Figure 290) and is the type genus for the family *Actinosynnemataceae* Labeda and Kroppenstedt (2000), now part of the family *Pseudonocardiaceae*.

FIGURE 288. Scanning electron micrograph of a synnemata from *Actinosynnema mirum*. Bar = 10 μm.

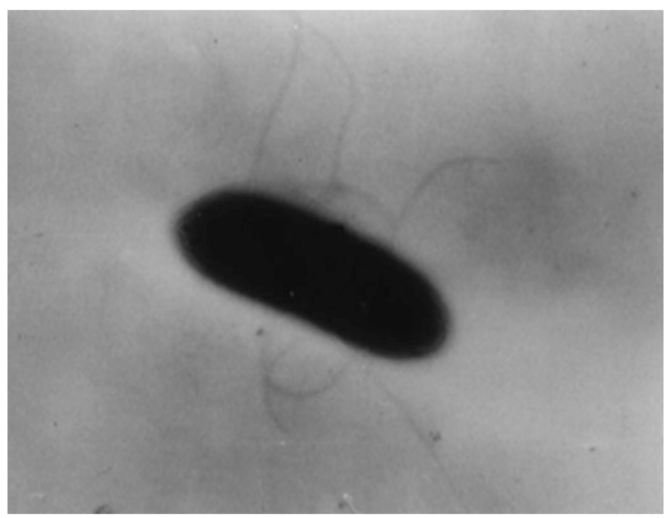

FIGURE 289. Electron micrograph of a zoospore of *Actinosynnema mirum*.

Enrichment and isolation procedures

Strains of the genus *Actinosynnema* can be isolated from grass blades by placing them on the surface of yeast extract agar plates (0.02% yeast extract and 1.5% agar in distilled water) and incubating for 3 weeks at 28°C. The agar surface will most likely be covered with various types of microbial growth, but small synnemata can be observed on the grass blade itself using a stereoscopic microscope. These synnemata can be carefully removed with a sterile loop and transferred to fresh growth media. *Actinosynnema mirum* has been reported not to be inhibited by the presence of 100 μg/ml nystatin or 50 μg/ml candicidin and *Actinosynnema pretiosum* has been found to be resistant to 100 μg/ml amphotericin B so it might be possible to use these antibiotics to suppress the growth of fungal competitors. Hayakawa et al. (2000) described an isolation method for strains of *Actinokineospora* and other actinomycetes that have motile zoospores which has also been reported to permit the isolation of *Actinosynnema* strains from soils and plant material. They placed a 0.5 g sample of air-dried soil or leaf litter in a beaker and gently flooded it with 50 ml sterile 10 mM phosphate buffer (pH 7.0) containing 10% soil extract. After incubating the sample for 90 min at 30°C, the motile zoospores that might be present are released. Following

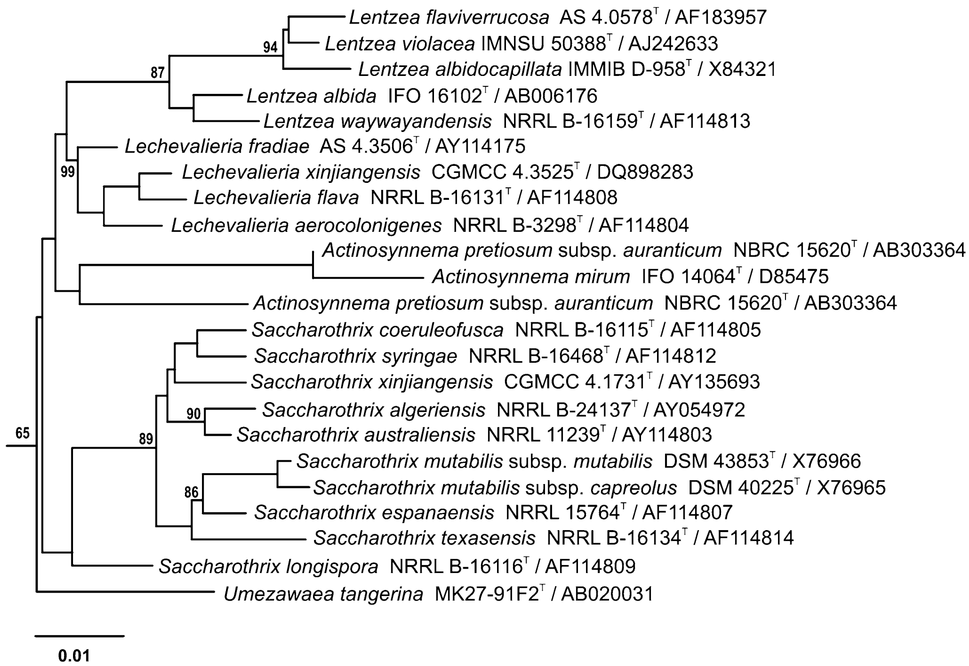

FIGURE 290. Phylogenetic tree for the genera *Actinosynnema*, *Lechevalieria*, *Lentzea*, *Saccharothrix*, and *Umezawaea* of the suborder *Pseudonocardineae* (now order *Pseudonocardiales*) calculated from almost-complete 16S rRNA gene sequences using the Kimura's evolutionary distance method (Kimura, 1980) and the neighbor-joining algorithm of Saitou and Nei (1987). Percentages at the nodes represent levels of bootstrap support (Felsenstein, 1989) from 100 resampled datasets; values less than 60% are not shown. Bar = 0.01 nucleotide substitutions per site.

low speed (i.e. 1,500 × *g*) centrifugation for 20 min and a subsequent 30 min incubation period, the samples are serially diluted and 200 µl aliquots plated onto an appropriate isolation medium such as HV medium (Hayakawa and Nonomura, 1987) containing 50 µg/ml cycloheximide with and without trimethoprim (20 µg/ml) and nalidixic acid (10 µg/ml). After a 2–3 week incubation period at 30°C, the plates are observed for the presence of synnemata using a microscope fitted with a long working distance objective and those observed can be transferred to fresh media.

Maintenance procedures

Working cultures of *Actinosynnema* can be maintained as plate or agar slant cultures on an appropriate medium such as NZamine agar (DSMZ medium 554; DSMZ, 2001) with bi-weekly subculturing. Survival of the cultures is often better at room temperature than at 4°C. Longer term preservation of strains is best accomplished as frozen stocks in 40% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques.

Procedures for testing special characters

Strains are routinely cultivated on NZamine medium (DSMZ medium 554) at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and NZamine medium, but for production of synnemata, strains should be grown on plates of 1.5% agar in tap water or Bennett's agar (DSMZ medium 548). Chemotaxonomic analysis of strains for fatty acids, polar lipids, and menaquinones are performed using methods described previously by Grund and Kroppenstedt (1989), Minnikin et al. (1984), Saddler et al. (1991), and Sasser (1990).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, guanine, hippurate, hypoxanthine, tyrosine, xanthine, and urea are typically determined using the media of Gordon et al. (1974). Phosphatase activity is evaluated by using the method of Kurup and Schmitt (1973) substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of NZamine medium and salt tolerance is evaluated on slants of the same medium supplemented with 2% to 5% NaCl.

Differentiation of the genus *Actinosynnema* from other genera

Strains of *Actinosynnema* can be differentiated easily from other actinomycetes by observation of the very characteristic synnemata produced on most growth media. Numerous other actinomycete genera produce motile zoospores, notably *Actinokineospora*, *Actinoplanes*, *Planobispora*, *Planomonospora*, *Spirillospora*, and several others, but none produce synnemata. The chemotaxonomic profile of *Actinosynnema* species is different from those of members of the other genera in the *Actinosynnemataceae*, particularly the whole-cell sugar pattern consisting of only galactose and mannose as the diagnostic sugars. The phospholipid pattern of *Actinosynnema* strains is quite similar to those of *Saccharothrix* species, but the lack of rhamnose in the whole-cell sugar pattern and the presence of MK-9(H_6) and lack of MK-10(H_4) menaquinones differentiates them from members of this genus. Characteristics of *Actinosynnema* and some related genera are given in Table 234.

Differentiation of the species of the genus *Actinosynnema*

The physiological characteristics of *Actinosynnema* species are summarized in Table 235 and can be used to differentiate between species, although a common set of physiological tests has not been used in the description of all species. Gross colonial morphology provides some additional information of the species based on the color of the substrate mycelium, production and color of aerial mycelium, and production and color of soluble pigments when growing on agar media.

TABLE 234. Chemotaxonomic and morphological characteristics of *Actinosynnema* and related genera[a,b]

Characteristic	*Actinosynnema*	*Lechevalieria*	*Lentzea*	*Saccharothrix*	*Umezawaea*
Production of synnemata and motile zoospores	+	–	–	–	–

List of species of the genus *Actinosynnema*

1. **Actinosynnema mirum** Hasegawa, Lechevalier and Lechevalier 1978, 305[AL]

mi′rum. L. neut. adj. *mirum* marvellous.

Substrate mycelium is yellow to orange-yellow in color, producing whitish synnemata that become yellow to orange-yellow in color on some media, notably thin potato-carrot agar of Higgins et al. (1967). White to yellowish-white aerial mycelia are produced on most media. A pale yellow-brown soluble pigment is produced on tyrosine agar and a pale greenish pigment on oatmeal agar.

Lactate, malate, pyruvate, and tartrate are assimilated for growth, but not acetate, benzoate, citrate, or succinate. Acid is produced from adonitol, L-arabinose, cellobiose, dextrin, fructose, galactose, glucose, glycogen, lactose, maltose, D-mannitol, D-mannose, D-melibiose, raffinose, L-rhamnose, soluble starch, sucrose, trehalose, and xylose, but not from dulcitol, erythritol, *i*-inositol, inulin, glycerol, methyl α-D-glucoside, methyl α-D-mannoside, D-ribose, salicin, or sorbitol. Temperature for growth is 28–30°C.

Source: isolated from a sedge (grass) blade.

DNA G+C content (mol%): 73 ± 1 (T_m).

Type strain: ATCC 29888, DSM 43827, NBRC 14064, IMRU 3971, JCM 3225, NRRL B-12336, VKM Ac-843.

Sequence accession no. (16S rRNA gene): D85475.

2. **Actinosynnema pretiosum** Hasegawa, Tanida, Hatano, Higashide and Yoneda 1983b, 314[VP]

pre.ti.o′sum. L. neut. adj. *pretiosum* precious.

2a. **Actinosynnema pretiosum subsp. pretiosum** Hasegawa, Tanida, Hatano, Higashide and Yoneda 1983b, 317[VP]

pre.ti.o′sum. L. neut. adj. *pretiosum* precious.

Substrate mycelium is pale yellow to pale orange-yellow in color. Branched hyphae in liquid culture fragment into motile elements with peritrichous flagella. The aerial mycelium consists of long, straight, helical, or (rarely) branching hyphae that are white to pale yellow in color. The aerial hyphae form in tufts at the tips of synnemata or on the surface of dome-like or irregular structures on the surface of the colonies. The aerial hyphae have a bamboo-like appearance and transform into chains of peritrichously flagellated spores. Yellow soluble pigments are produced on glucose-asparagine and peptone-yeast extract agars. The type strain produces antibiotics of the ansamitocin complex and tomaymycin. Temperature for growth is 28–30°C.

Source: isolated from a blade of *Carex* grass.

DNA G+C content (mol%): 71 ± 1 (T_m).

Type strain: C-15003(N-1), ATCC 31281, DSM 44132, FERM-P 3992, NBRC 15621, JCM 7344, NRRL B-16060, VKM Ac-1963.

Sequence accession no. (16S rRNA gene): AF114800.

2b. **Actinosynnema pretiosum subsp. auranticum** Hasegawa, Tanida, Hatano, Higashide and Yoneda 1983b, 320[VP]

au.ran′ti.cum. N.L. neut. adj. *auranticum* orange.

Substrate mycelium is yellowish-orange or orange on various media. Aerial hyphae are white to yellowish white in color. Pale yellowish-brown soluble pigments are produced on several media. The type strain produces the antibiotics dnacins and ansamitocins. Temperature for growth is 28–30°C.

Source: isolated from a blade of *Carex* species grass.

DNA G+C content (mol%): 71 ± 1 (T_m).

Type strain: C-14482(N-1001), ATCC 31309, DSM 44131, FERM-P 4130, NBRC 15620, JCM 7343, NRRL B-16078, VKM Ac-1961.

Sequence accession no. (16S rRNA gene): AB303364.

Genus V. **Amycolatopsis** Lechevalier, Prauser, Labeda and Ruan 1986, 34[VP] emend. Lee 2009, 1403

Geok Yuan Annie Tan and Michael Goodfellow

A.my.co.la.top′sis. N.L. fem. n. *Amycolata* genus belonging to the order *Actinomycetales*; Gr. fem. n. *opsis* aspect, appearance; N.L. fem. n. *Amycolatopsis* that which appears similar to *Amycolata*.

Aerobic to facultatively anaerobic, Gram-stain-positive, non-acid-fast, nonmotile, catalase-positive actinomycetes that form branching substrate hyphae which fragment into squarish and rod-shaped elements. When formed, aerial hyphae may be sterile or differentiate into chains of smooth-walled, squarish to ellipsoidal spore-like structures. Chemo-organotrophic to facultatively autotrophic. Grows on a broad range of organic and synthetic media. Mesophilic or thermophilic. **Whole-organism hydrolysates are rich in *meso*-2,6-diaminopimelic acid, arabinose, and galactose.** The peptidoglycan is of the A1γ type. Muramic acid moieties are *N*-acetylated. **The diagnostic phospholipid is phosphatidylethanolamine (with or without phosphatidylmethylethanolamine) or phosphatidylmethylethanolamine** with variable occurrence of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides; contains **complex mixtures of saturated and branched chain fatty acids**. Does not contain mycolic acids. The phylogenetic position of *Amycolatopsis,* as determined by 16S rRNA gene sequence analysis, is in the family *Pseudonocardiaceae.*

Common in arid soils but has also been isolated from activated sludge, equine placentas, and from clinical and plant material.

DNA G+C content (mol%): 66–75 (T_m; HPLC).

Type species: **Amycolatopsis orientalis** (Pittenger and Brigham 1956) Lechevalier, Prauser, Labeda and Ruan 1986, 35[VP].

Further descriptive information

Phylogeny. The genus *Amycolatopsis* forms a clade in the *Pseudonocardiaceae* 16S rRNA gene tree. It encompasses 39 species with validly published names, most of which have been proposed in the past five years using polyphasic taxonomic approaches (Carlsohn et al., 2007; Labeda et al., 2003; Lee, 2009; Tan et al., 2006a, 2007). These species can be assigned to five multimembered and two single-membered phyletic lines in the *Amycolatopsis* 16S rRNA gene tree (Figure 291). The taxonomic integrity of the multimembered taxa, the *Amycolatopsis methanolica*, *Amycolatopsis nigrescens*, *Amycolatopsis orientalis*, *Amycolatopsis palatopharyngis*, and *Amycolatopsis sulphurea* subclades, are supported by all of the tree-making algorithms and by high bootstrap values.

Amycolatopsis methanolica subclade strains grow well at temperatures up to 60°C (Chun et al., 1999; De Boer et al., 1990; Henssen et al., 1987; Kim et al., 2002a) and can thereby be considered to be thermophilic actinomycetes (Brock, 1986; Cross, 1968). Further comparative taxonomic studies between members of this and the other multimembered subclades are needed to determine whether the *Amycolatopsis methanolica* subclade merits generic status. The type strain of *Amycolatopsis fastidiosa*, now reclassified as *Actinokineospora fastidiosa*, which grows between 10 and 60°C, forms a distinct phyletic line at the foot of the *Amycolatopsis* 16S rRNA gene tree (Goodfellow et al., 2001; Huang et al., 2001, 2004; Labeda et al., 2010b).

Everest and Meyers (2009) found good congruence between 16S rRNA and partial *gyrB* phylogenies of representative *Amycolatopsis* strains. Differences were found between the overall topologies of the trees, though groups of closely related strains clustered together in both trees, a result consistent with corresponding studies on the genera *Gordonia* (Shen et al., 2006) and *Micromonospora* (Kasai et al., 2000). A concatenated tree based on *gyrB*/16S rRNA gene sequences closely resembled the *gyrB* tree and contained conserved phyletic lines evident in the separate trees. It was apparent that the number of phyletic lines supported by high bootstrap values was much greater in the concatenated gene tree than in the corresponding 16S rRNA and partial *gyrB* trees. The type strain of *Amycolatopsis fastidiosa* formed a distinct phyletic line outside the evolutionary radiation occupied by the other *Amycolatopsis* strains in both the partial *gyrB* and concatenated trees.

DNA–DNA relatedness studies show that the type strain of *Amycolatopsis fastidiosa* has little, if any, DNA in common with the other *Amycolatopsis* strains to which it has been compared (Table 236). This is also the case with the type strain of *Amycolatopsis sulphurea*, an organism which forms a distinct phyletic line with *Amycolatopsis jejuensis* NRRL B-24427[T] in the 16S rRNA/*gyrB* concatenated tree (Everest and Meyers, 2009) though its nearest neighbor in the 16S rRNA gene tree, *Amycolatopsis sulphurea*, was not included in this study. In general, good congruence exists between DNA–DNA pairing and corresponding 16S rRNA gene sequence data.

Cell morphology. *Amycolatopsis* strains show regular to occasional fragmentation of either the substrate mycelium or the aerial mycelium or both (Figure 292). They do not form sclerotia, spore vesicles, or synnemata. Kothe et al. (1989) examined the morphology and fine structure of members of the family *Pseudonocardiaceae* and found that *Amycolatopsis* strains produced long chains of smooth, squarish to ellipsoidal spore-like structures on substrate and aerial mycelia. They also noted that the fine structure of the hyphae varied as some *Amycolatopsis* strains produced an electron-dense layer that covered the hyphal wall but others did not. Some strains show an unusual degree of morphological variation, as exemplified by the formation of short chains of oval, smooth-surfaced spores on the substrate mycelium of *Amycolatopsis taiwanensis* KCTC 19116[T] (Figure 293) and the production of globose, smooth-surfaced pseudosporangia by *Amycolatopsis decaplanina* DSM 44594[T] (Figure 294). However, spores were not detected either inside or outside the pseudosporangiae (Wink et al., 2004).

Chemotaxonomy. *Amycolatopsis* strains have cell walls which contain *meso*-diaminopimelic acid (*meso*-A_2pm), arabinose, and galactose (Carlsohn et al., 2007; Lechevalier et al., 1986; Takeuchi et al., 1992), that is, they have a wall chemotype IV *sensu* Lechevalier and Lechevalier (1970); an A1γ type peptidoglycan (Schleifer and Kandler, 1972); muramic acid in the *N*-acetylated form (Lee and Hah, 2001; Tan et al., 2006a, 2007), and phosphatidylethanolamine (PE; taxonomically significant phospholipid) and phosphatidylglycerol (PG) as major polar lipids (phospholipid type II *sensu* Lechevalier et al., (1981, 1977a) with a variable occurrence of diphosphatidylglycerol (DPG), hydroxyphosphatidylethanolamine (HPE), phosphatidylinositol (PI), phosphatidylinositol mannosides (PIMs), phosphatidylserine (PS), and phosphatidylmethylethanolamine (PME). The type strains of *Amycolatopsis nigrescens* and *Amycolatopsis saalfeldensis*, for instance, contain DPG, PE, HPE, PG, PI, PS, and uncharacterized glycolipids (Carlsohn et al., 2007; Groth et al., 2007). Details of the polar lipid composition of individual species are given in the species descriptions.

In general, most *Amycolatopsis* species have di-, tetra-, or hexahydrogenated menaquinones with nine isoprene units [MK-9(H_2,H_4,H_6)] as the predominant isoprenologue (Alderson et al., 1981; Lechevalier et al., 1986; Tan et al., 2006a, 2006b, 2007; Wink et al., 2003b; Yassin et al., 1991). In contrast, *Amycolatopsis decaplanina* contains a mixture of tetrahydrogenated menaquinones with eight and nine isoprene units (Wink et al., 2004), whereas *Amycolatopsis nigrescens* is characterized by the presence of major amounts of tetrahydrogenated menaquinones with eleven isoprene units and corresponding components with nine, ten, and twelve isoprene units (Groth et al., 2007). Variations in the proportions of di-, tetra-, and hexahydrogenated components with nine isoprene units amongst several *Amycolatopsis* species were attributed to the collection of biomass from different stages of the growth cycle (Yassin et al., 1991).

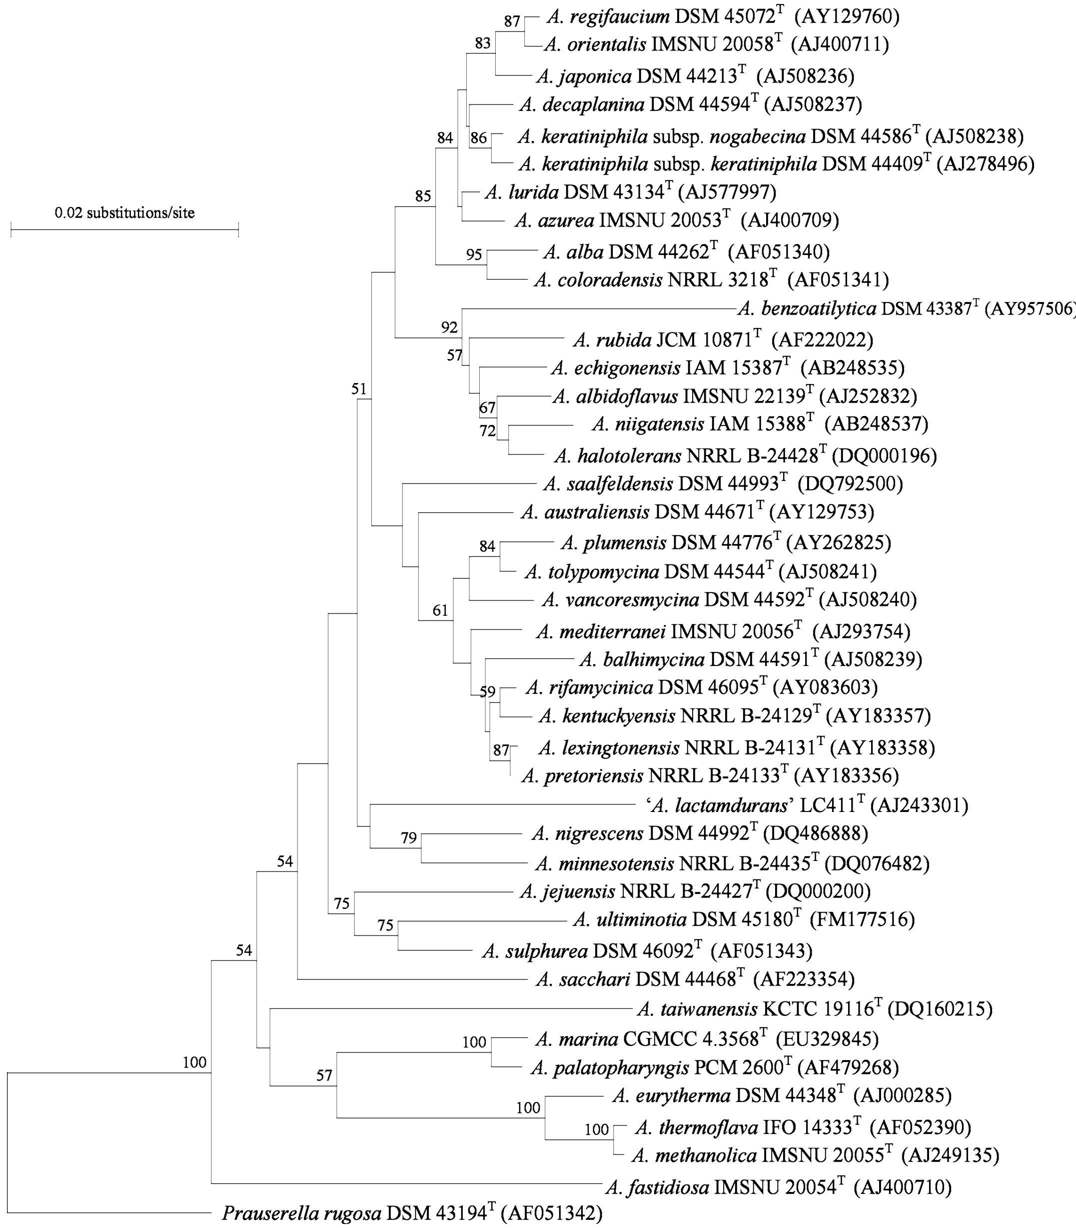

FIGURE 291. Neighbor-joining tree (Saitou and Nei, 1987) based on nearly complete 16S rRNA gene sequences showing relationships between the type strains of *Amycolatopsis* species. The numbers at the nodes indicate the levels of bootstrap support based on 1000 resampled datasets; only values above 50% are given. Bar = 0.02 substitutions per nucleotide position.

Amycolatopsis strains contain complex mixtures of iso-branched, straight chain saturated, and unsaturated components (Alderson et al., 1981; Kroppenstedt, 1985; Wink et al., 2003b; Yassin et al., 1993), but lack mycolic acids (Carlsohn et al., 2007; Huang et al., 2004; Lechevalier et al., 1986). Most strains have similar qualitative fatty acid profiles in which 14-methylpentadecanoic acid ($C_{16:0}$ iso) is the major component (Carlsohn et al., 2007; Kothe et al., 1989; Mertz and Yao, 1993; Wink et al., 2003b) though considerable amounts of hexadecanoic ($C_{16:0}$), 12-methyltridecanoic ($C_{14:0}$ iso), 13-methyltetradecanoic ($C_{15:0}$ iso), heptadecanoic ($C_{17:0}$), and octadecanoic ($C_{18:0}$) acids may be present (Huang et al., 2004; Lee, 2006; Lee and Hah, 2001). Quantitative differences in fatty acid profiles have been used to distinguish between *Amycolatopsis* species (Groth et al., 2007; Mertz and Yao, 1993).

Colony morphology. *Amycolatopsis* strains form well developed colonies on most standard media used to cultivate filamen-

[a]Data taken from Al-Musallam et al. (2003), Bala et al. (2004), Chun et al. (1999), Kim et al. (2002a), Labeda (1995), Lechevalier et al. (1986), Everest and Meyers (2009), Stackebrandt et al. (2004), Tan et al. (2007), and Wink et al. (2004).

FIGURE 292. Scanning electron micrograph of *Amycolatopsis orientalis* KCTC 9412^T showing the formation of squarish fragments from the mycelium after growth on modified Bennett's agar at 28°C for 14 d. Bar = 1.0 µm.

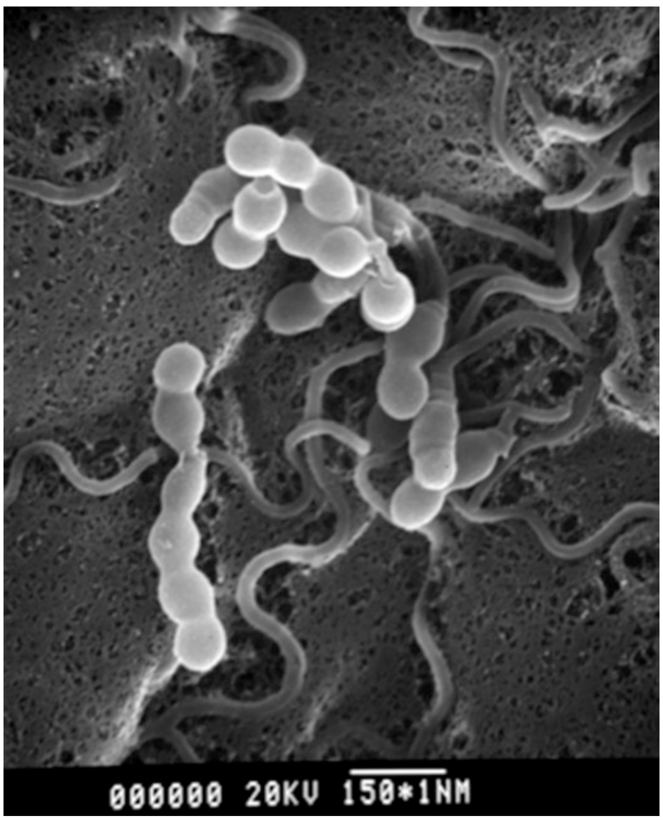

FIGURE 293. Scanning electron micrograph of *Amycolatopsis taiwanensis* KCTC 19116^T showing the formation of spore chains following growth on HV agar at 28°C for 14 d. Bar = 1.5 µm (Reproduced with permission of Tseng et al., 2006. Int. J. Syst. Evol. Microbiol. *56*: 1811–1815.)

tous actinomycetes and may carry abundant aerial hyphae (Mertz and Yao, 1993; Wink et al., 2003b, 2004). They grow particularly well on modified Bennett's agar supplemented with mannitol

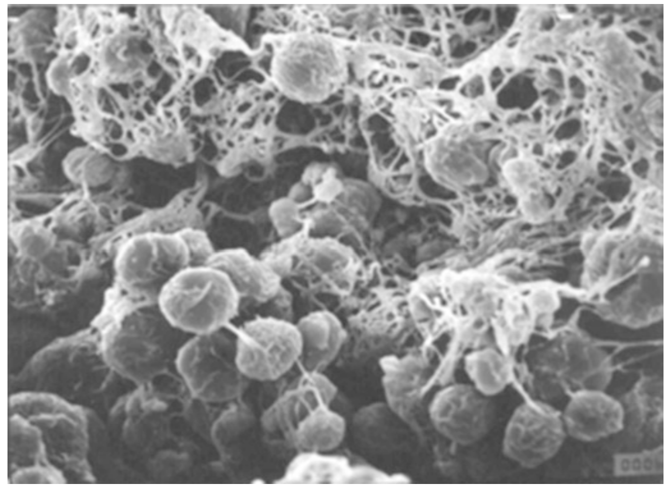

FIGURE 294. Scanning electron micrograph (×1000) of *Amycolatopsis decaplanina* DSM 44594^T showing the formation of pseudosporangiae following growth on oatmeal agar at 28°C for 14 d (Reproduced with permission from Wink et al., 2004. Int. J. Syst. Evol. Microbiol. *54*: 235–239.)

(0.5%, w/v) and soybean flour (0.5%, w/v) following incubation at 28°C for 14 d (Tan et al., 2006b). Tan and her colleagues were able to assign strains growing under these conditions to 35 color-groups based on aerial hyphal color, substrate mycelial pigmentation, and diffusible pigment color. Strains taken to represent many of the color groups formed distinct phyletic lines in the 16S rRNA *Amycolatopsis* gene tree indicating that color groupings can be predictive from a taxonomic perspective. Isolates assigned to two of these color groups were subsequently classified as novel *Amycolatopsis* species, namely *Amycolatopsis australiensis* and *Amycolatopsis regifaucium* (Tan et al., 2006a, 2007).

Nutrition and growth conditions. *Amycolatopsis* strains grow well on standard media such as glycerol-asparagine, inorganic-salts starch, oatmeal, peptone-yeast extract-iron, tyrosine, tryptone-yeast extract and yeast extract-malt extract agars (ISP media 2–7; Shirling and Gottlieb, 1966), and on modified Bennett's agar supplemented with mannitol and soybean flour (Tan et al., 2006b). *Amycolatopsis eurytherma*, *Amycolatopsis fastidiosa*, *Amycolatopsis methanolica*, and *Amycolatopsis thermoflava* strains grow well at 50°C or above (Chun et al., 1999; De Boer et al., 1990; Henssen et al., 1987; Kim et al., 2002a) and can be considered to be thermophilic actinomycetes (Brock, 1986; Cross, 1968). A fourth species, *Amycolatopsis sacchari*, contains organisms that are moderate thermophiles (Goodfellow et al., 2001). In contrast, organisms assigned to the remaining *Amycolatopsis* species are mesophiles (Lee and Hah, 2001; Tan et al., 2006a, 2007). *Amycolatopsis* strains grow well from pH 6.0 to 9.0.

Metabolism. *Amycolatopsis* strains are aerobic to facultatively anaerobic, chemo-organotrophic to facultatively autotrophic actinomycetes that degrade several organic substrates, produce acid from a range of sugars, and use diverse compounds as sole sources of carbon for energy and growth (Chun et al., 1999; De Boer et al., 1990; Gordon et al., 1978; Groth et al., 2007). The

TABLE 237. Bioactive compounds produced by members of the genus *Amycolatopsis*

Strain/taxon	Product	Feature	Reference
A. alba	Glycopeptide antibiotic	Inhibits peptidoglycan synthesis	Mertz & Yao (1993)
A. azurea	Azureomycins A and B	Glycopeptide antibiotics	Ōmura et al. (1979)
A azurea	Octacosamicins	Antifungal activity	Dobashi et al. (1988)
A. balhimycina	Balhimycin	Glycopeptide antibiotic	Nadkarni et al. (1994)
A. coloradensis	Avoparcin	Glycopeptide antibiotic	Kunstmann et al. (1968)
A. fastidiosa	Antibiotics 41034 and 41494	Macrobicyclic peptides	Celmer et al. (1977)
A. japonica	*(S,S)-N,N′*-ethylene-diaminedisuccinic acid	Inhibits phospholipase C	Nishikori et al. (1984)
	Dethymicin	Immunosuppressant	Ueno et al. (1992)
A. keratiniphila subsp. *nogabecina*	Nogabecin	Glycopeptide antibiotic	Shorin et al. (1957)
"*A. lactamdurans*"	Cephamycin C	β-Lactam antibiotic	Stapley et al. (1972)
	Efrotomycin	β-Isomer	Wax et al. (1976)
	3-Methylpseudouridine	Polyether	Nielsen and Arison (1989)
A. mediterranei	Rifamycins	Clinically useful ansamycins, active against *Mycobacterium* spp.	Margalith and Beretta (1960); Lancini et al. (1967); Birner et al. (1972); Lancini and Sartori (1976)
	31-Homorifamycin W		Wang et al. (1994)
	Kanglemycin A	Ansamycin-type antibiotic	Wang et al. (1988)
	Dethymicin	Immunosuppressant	Ueno et al. (1992)
	3-Hydroxyrifamycin S	Ansamycin antibiotic	Traxler et al. (1981)
	Protorifamycins	Ansamycin antibiotics	Ghisalba et al. (1978, 1979, 1980)
	Aromatic amino acids	Suitable for strain improvement	de Boer et al. (1990)
A. orientalis	Vancomycin	Glycopeptide antibiotic, active against severe bacterial infections	Pittenger and Brigham (1956)
	Glycopeptide compounds	Glycosyltransferase gene, *gtfA*	Baltz (2000)
	Muraceins	Muramyl peptide inhibitors	Bush et al. (1984)
	N-Demethylvancomycin	Vancomycin analog	Boeck et al. (1984)
	D-Amino acid specific peptidase		Sugie et al. (1988)
	MM47761, MM49721, MM55266, MM55268	Glycopeptide antibiotics	Box et al. (1991, 1990)
	Orienticin	Glycopeptide antibiotic	Tsuji et al. (1988)
	Quartromicin	Antiviral antibiotics	Tsunakawa et al. (1992)
	Antibiotic UK-69753	Efrotomycin-like antibiotic	Ruddock et al. (1987); Pacey et al. (1989)
A. lurida	Benzathrins	Quinone antibiotic with antitumor activity	Philip et al. (1957); Theriault et al. (1986); Rasmussen et al. (1986)
	Ristocetin	Glycopeptide antibiotic	Grundy et al. (1957)
A. regifaucium	Kigamicins	Antitumor antibiotics	Kunimoto et al. (2003)
A. sulphurea	Cetocycline	Tetracycline derivative	Proctor et al. (1978)
A. tolypomycina	Tolypomycin	Ansamycin-type antibiotic	Hasegawa et al. (1971); Kishi et al. (1972)
A. vancoresmycina	Homorifamycin; vancoresmycin	Ansamycin antibiotic; polyketide antibiotic	Hopmann et al. (2002).

type strain of *Amycolatopsis benzoatilytica* metabolizes *m*-hydroxybenzoate through a central protocatechuate intermediate, unlike other *Amycolatopsis* species which are unable to use this compound as growth substrate (Grund et al., 1990).

Members of the genus are a rich source of antibiotics and secondary metabolites (Table 237). Medically important antibiotics produced by *Amycolatopsis* strains include balhimycin (Nadkarni et al., 1994), dethymicin (Ueno et al., 1992), rifamycin (Sensi et al., 1959), and vancomycin (Barna and Williams, 1984). Balhimycin and vancomycin show antibiotic activity against methicillin-resistant *Stapylococcus aureus* strains, whereas dethymicin has a mode of action which distinguishes it from other immunosuppresants, such as cyclosporine, FK506, and rapamycin. Rifamycin is used to treat leprosy and tuberculosis, and to control infections in organ implants and AIDS patients.

Much of the emphasis in studies on the metabolism of *Amycolatopsis* strains has been focused on the application of biochemical and genetic approaches to the synthesis of antibiotics, as exemplified by studies on the biosynthesis of rifampin (Floss and Yu, 2005; Ghisalba and Nuesch, 1981; Hu et al., 1999; Schupp et al., 1998; Xu et al., 2005). The polyketide framework of rifamycin B is assembled from 3-amino-5-hydroxybenzoic acid (AHBA), a product of the aminoshikimate pathway (Kim et al., 1998; Yu et al., 2001), two molecules of acetate and eight of

propionate. Five multifunctional proteins (RifA–RifE) and an amide synthase (RifF) catalyze the synthesis of the core structure of rifampin (August et al., 1998; Schupp et al., 1998; Xu et al., 2005).

A number of non-antibiotic bioactive metabolites are formed by *Amycolatopsis* strains, including (*S,S*)-*N,N*′-ethylenediamine disuccinic acid from *Amycolatopsis japonica* (Nishikori et al., 1984), a D-amino acid-specific peptidase from *Amycolatopsis orientalis* (Sugie et al., 1988), and a polylactic acid depolymerase from *Amycolatopsis* sp. strain K104-1 (Nakamura et al., 2001). *Amycolatopsis orientalis* produces chitinases of potential value in the production of chitin hexamers (Tominaga and Tsujisaka, 1976; Usui et al., 1987); this organism converts tetra-*N*-acetylchitotelraose to a mixture of hexa-*N*-acetyl-chitohexaose and the corresponding dimer by a transglycosylation reaction (Usui et al., 1987). *Amycolatopsis* sp. strain HR167 is used to produce vanillic acid from ferulic acid (Rabenhorst and Hopp, 1997), and an *Amycolatopsis* isolate for the bioconversion of lovastatin to the novel compound wuxistatin (Zhuge et al., 2008).

Amycolatopsis methanolica NCIB 11946^T is a facultative methylotrophic actinomycete which was previously assigned to the genera *Nocardia* and *Streptomyces* (De Boer et al., 1990). The organism assimilates formaldehyde by the ribulose monophosphate shunt (Hazeu et al., 1983), a finding that made it a candidate for fermentative overproduction of aromatic amino acids (Dijkhuizen et al., 1985; Morinaga and Hirose, 1984). Regulation of aromatic amino acid biosynthesis in the strain has been studied in detail (Abou-Zeid et al., 1995; De Boer et al., 1989; Euverink et al., 1992, 1995) and stable mutants have been isolated and grown under diverse conditions in batch and continuous culture (De Boer et al., 1988; Hazeu et al., 1983). Prephenate dehydratase (PDT) is a key regulatory enzyme in L-phenylalanine biosynthesis, the PDT protein of which has been purified and characterized as a homotetrameric enzyme with 34 kDa subunits (Euverink et al., 1995). It has been shown that *Amycolatopsis methanolica* metabolizes glucose via the Embden–Meyerhof–Parnas pathway (Alves et al., 1994), and produces a PPi-dependent phosphofructokinase with biochemical characteristics similar to both ATP- and PPi-dependent enzymes during growth on glucose (Alves et al., 1996).

A copper-resistant *Amycolatopsis* strain was isolated from copper-polluted sediment by Albarracin et al. (2008). The organism accumulates high levels of copper and is considered to have potential as an agent of bioremediation. It was subsequently characterized and described as a novel *Amycolatopsis* species, *Amycolatopsis tucumanensis* (Albarracin et al., 2010). These workers also found that the type strain of *Amycolatopsis eurytherma*, a close relative of *Amycolatopsis tucumanensis*, has a moderate copper resistance profile.

Genetics. Genetic analyses show that the antibiotic potential of members of the genus *Amycolatopsis* is much greater than previously recognized (Banskota et al., 2006; Wood et al., 2007). Improved genetic tools, including new cloning, expression, and shuttle vectors are being developed to manipulate and regulate genes involved in secondary metabolite production and to gain an insight into the origin, evolution, and functional properties of extrachromosomal elements (Malhotra and Lal, 2007; te Poele et al., 2007, 2008).

Amycolatopsis methanolica NCIB 11946 contains a 13.3 kb conjugative element, pMEA300, which is maintained as an integrated element, but may also be present as a free circular plasmid (Malhotra and Lal, 2007; te Poele et al., 2007, 2008). Various cloning vectors based on these plasmids have been constructed (Madón and Hutter, 1991; Vrijbloed et al., 1995a), and used to clone genes involved in glucose and methanol metabolism and in aromatic amino acid biosynthesis into *Amycolatopsis methanolica* (Alves et al., 1996; Hektor, 1997; Vrijbloed et al., 1995c, 1995d). The conjugative element pMEA100 (23.7 kb) from *Amycolatopsis mediterranei* LBG A3136 also exists in an integrated form and in the free state, but in *Amycolatopsis mediterranei* ATCC 13685 it is only found in the free form (Moretti et al., 1985).

The integrated elements of *Amycolatopsis mediterranei* and *Amycolatopsis methanolica* have been sequenced (te Poele et al., 2006; te Poele et al., 2008; Vrijbloed, 1996), and on the basis of structural and functional similarities shown to belong to a class of integrative and conjugative elements (ICEs; Moretti et al., 1985; Burrus et al., 2002) that have been found in several other filamentous actinomycetes, such as pSE211 and pSE101 from *Saccharopolyspora erythraea* (Brown et al., 1988, 1994), pSAM2 from *Streptomyces ambofaciens* (Boccard et al., 1989; Pernodet et al., 1984; Smokvina et al., 1991), SLP1 from "*Streptomyces coelicolor*" A3(2) (Bibb et al., 1981) and pSG1 from *Streptomyces griseus* (Cohen et al., 1985). This class of elements integrate site-specifically in a tRNA gene of the host genome, but unlike other ICEs, replicate autonomously like a plasmid. Most are self-transmissible and several can mobilize chromosomal markers (Bibb et al., 1981; Brown et al., 1988; Hopwood et al., 1984; Moretti et al., 1985; Smokvina et al., 1988; Vrijbloed, 1996). The integrase (Int) directs site-specific DNA recombination between the attP site and a chromosomal attB site (Boccard et al., 1989).

Characterization of deletion derivatives of pMEA300 led to the identification of genes needed for replication, regulation, integration, and conjugation (Vrijbloed et al., 1994, 1995a, 1995b, 1995c, 1995d). The organization of genes involved in replication, excision, and integration (attp, int, repAM, xis) in pMEA300 is conserved (te Poele et al., 2007, 2008). It has been shown that most of these elements can mediate the pock-formation phenotype, reflecting growth retardation of the recipient which occurs during conjugation (Vrijbloed et al., 1995b). These workers found that the *traJ* gene was required for the transfer of pMEA300 into recipient strains lacking this element. TraJ of pMEA300 shows 33% identity to TraJ of pMEA100 (te Poele et al., 2008) and 27% identity to a cell division FtsK/SpoIII protein of *Frankia* strain EAN1 pec, and to TraB of *Streptomyces ghanaenis* plasmid pS65 (te Poele et al., 2007). This latter protein is a septal DNA translocator which mediates a unique conjugation mechanism that translocates unprocessed double-stranded DNA molecules to recipient strains (Reutler et al., 2006).

te Poele et al. (2007, 2008) determined the presence and distribution of a new class of replication initiator and transfer proteins, namely RepAM and TraJ. They screened a collection of over 100 *Amycolatopsis* strains that had been isolated from different geographical locations and found pMEA sequences to be widely distributed. They identified two geographically distinct pMEA-like elements. Phylogenetic analysis of their deduced RepAM and TraJ protein sequences revealed clusters with protein sequences of either pMEA100 or pMEA300. The sequences which clustered with pMEA100 were from European strains and

those from pMEA300 encompassed Australasian strains. The *repAM* and *traJ* genes were linked with the 16S rRNA genes of the host strains suggesting that the pMEA-elements co-evolved with their hosts rather than being dispersed by horizontal transfer of the free replicating form.

Amycolatopsis benzoatilytica (previously *Amycolatopsis orientalis*) DSM 43387^T (Majumdar et al., 2006) contains a 29.6 kb non-integrative, freely replicating plasmid, pA387 (Lal et al., 1991). This plasmid has been completely sequenced and used to construct cloning and conjugative shuttle vectors (Lal et al., 1991; Malhotra et al., 2008) and to generate *Escherichia coli–Amycolatopsis* shuttle vectors (Ding et al., 2003; Khanna et al., 1998; Kumar et al., 1994; Lal et al., 1998; Priefert et al., 2002; Tuteja et al., 2000). These vectors replicate and are maintained in members of several *Amycolatopsis* species, including *Amycolatopsis japonica* (Stegmann et al., 2001), "*Amycolatopsis lactamdurans*" (Kumar et al., 1994), *Amycolatopsis mediterranei* (Ding et al., 2003; Lal et al., 1991, 1998; Tuteja et al., 2000), *Amycolatopsis orientalis* (Lal et al., 1991), and *Amycolatopsis rifamycinica* (Khanna et al., 1998; Lal et al., 1998; Tuteja et al., 2000). The value of pA387-derived shuttle vectors has been demonstrated in several studies (Kumar et al., 1996; Xu et al., 2005), notably by increased production of cephamycin C by "*Amycolatopsis lactamdurans*" (Chary et al., 1997, 2000).

The direct mycelium transformation system developed for *Amycolatopsis mediterranei* by Madón and Hütter (1991) was applied and optimized to enhance the conversion of ferulic acid into vanillin using *Amycolatopsis* sp. strain HR 167 (Priefert et al., 2002). The density of the mycelial suspensions in the transformation mixture and the methylation state of the plasmid DNA used for the transformation were critical factors. The transformation rates achieved with plasmid DNA isolated from *Escherichia coli* ET 12567 was 3,500-fold higher than those obtained with DNA isolated from *Escherichia coli* XLI-Blue. Other interesting developments include the isolation of balhimycin genes from *Amycolatopsis mediterranei* using a reverse cloning procedure (Pelzer et al., 1999), the discovery that the *pfp* gene of *Amycolatopsis methanolica*, which encodes PPi-dependent phosphofructokinase, is located on a 2.3 kb *Pvu*II fragment (Alves et al., 1996), and the detection of genes involved in the modification of the polyketide backbone of rifamycin B by *Amycolatopsis mediterranei* S699 (Xu et al., 2005).

Antibiotic sensitivity. Comprehensive comparative studies on the antibiotic sensitivity patterns of all *Amycolatopsis* species are needed now that there is evidence that members of this genus may be considered as emerging pathogens. Preliminary studies show that closely related *Amycolatopsis* species can be distinguished using antibiotic sensitivity data (De Boer et al., 1990).

Pathogenicity. There is no conclusive evidence that *Amycolatopsis* strains can cause disease in humans, although the type strain of *Amycolatopsis benzoatilytica* has been implicated as an agent of submandibular mycetoma (Majumdar et al., 2006; Scharfen, 1971). In addition, members of the genus are occasionally encountered in clinical material (Mishra et al., 1980; Schaal and Beaman, 1984). *Amycolatopsis orientalis* has been isolated from cerebrospinal fluid (Gordon et al., 1978) and *Amycolatopsis palatopharyngis* has been isolated from infected palatopharyngeal mucosa of a 70-year-old male (Huang et al., 2004). There is evidence that actinomycetes can cause placentitis and abortion in horses (Donahue and Williams, 2000; Giles et al., 1993; Hong et al., 1993). The distinctive type of nocardiosis in horses, nocardioform placentitis, is recognized by the formation of lesions on the chorionic surface of the placenta and the isolation of Gram-stain-positive, branching bacteria. Three *Amycolatopsis* species, *Amycolatopsis kentuckyensis*, *Amycolatopsis lexingtonensis*, and *Amycolatopsis pretoriensis*, were proposed to accommodate strains isolated from equine placentas (Labeda et al., 2003).

Ecology. Most members of the genus *Amycolatopsis* have been isolated from soil and vegetable matter though their roles in these environments have not been studied. It seems likely that the primary habitat is soil, as exemplified by the isolation of *Amycolatopsis australiensis* from an arid composite soil (Tan et al., 2006a), *Amycolatopsis eurytherma* from scrubland soil (Kim et al., 2002a), *Amycolatopsis keratiniphila* from marsh soil (Al-Musallam et al., 2003), *Amycolatopsis plumensis* from a brown hypermagnesian ultramafic soil (Saintpierre-Bonaccio et al., 2005), *Amycolatopsis rubida* from a coniferous forest soil (Huang et al., 2001), and *Amycolatopsis ultiminotia* from rhizosphere soil (Lee, 2009). Additional *Amycolatopsis* species have been recovered from more unusual sources, such as the isolation of *Amycolatopsis echigonensis* from a filtrate substrate (Ding et al., 2007), *Amycolatopsis jejuensis* from a natural cave (Lee, 2006), *Amycolatopsis nigrescens* from a Roman catacomb (Groth et al., 2007), *Amycolatopsis saalfeldensis* from a medieval alum slate mine (Carlsohn et al., 2007), and *Amycolatopsis tucumanensis* from copper-polluted sediments (Albarracin et al., 2010). *Amycolatopsis* strains have also been isolated from hyper-arid soils of the Atacama Desert (Okoro et al., 2009).

Large numbers of *Amycolatopsis* strains have been recovered from Australian arid soils, and from an environmental sample collected from under a sycamore tree in Newcastle-upon-Tyne, UK, using a dilution plate procedure and three selective media (Tan et al., 2006b). Many of the isolates were related to either *Amycolatopsis mediterranei* or *Amycolatopsis orientalis* on the basis of 16S rRNA gene sequencing, but others formed new phyletic lines. Some of the novel isolates were classified as *Amycolatopsis australiensis* sp. nov. (Tan et al., 2006a) and *Amycolatopsis regifaucium* sp. nov. (Tan et al., 2007).

Enrichment and isolation procedures

Members of most *Amycolatopsis* species have been isolated by plating dilutions of soil suspensions onto nonselective media, supplemented with antifungal antibiotics, followed by colony selection and characterization. This hit and miss approach, for instance, led to the isolation of *Amycolatopsis halotolerans* and *Amycolatopsis jejuensis* on starch-casein agar (Lee, 2006), *A mediterranei* on Bennett's agar (Margalith and Beretta, 1960), *Amycolatopsis nigrescens* on nutrient agar (Groth et al., 2007), *A rubida* on glucose-asparagine agar (Huang et al., 2001), *Amycolatopsis saalfeldensis* on casein mineral agar (Carlsohn et al., 2007), and *Amycolatopsis taiwanensis* on HV agar (Tseng et al., 2006); in the main, isolation plates were incubated at either 28°C or 30°C for 14 d.

Several *Amycolatopsis* species have been isolated from environmental samples using less subjective isolation procedures. *Amycolatopsis keratiniphila* was isolated from soil enriched with

sterilized and defatted wool (Al-Musallam et al., 2003), *Amycolatopsis palatopharyngis* was isolated on brain-heart infusion agar at 37°C for 5 d under microaerophilic conditions (Huang et al., 2004), and *Amycolatopsis plumensis* was isolated on yeast extract-malt extract agar supplemented with streptomycin (Saintpierre-Bonaccio et al., 2005). In addition, *Amycolatopsis sacchari* strains were recovered from diverse environmental samples using a wind tunnel technique (Lacey, 1971; Lacey and Dutkiewicz, 1976a); the Andersen sampler was loaded with Petri dishes containing half-strength nutrient agar (Goodfellow et al., 2001).

Tan et al. (2006b) designed a number of agar media to isolate *Amycolatopsis* strains from soil using putative selective agents drawn from phenotypic databases generated in numerical taxonomic studies on members of the family *Pseudonocardiaceae.* Three of the resultant media formulations proved to be particularly effective in recovering *Amycolatopsis* strains from soil samples, namely media SM1 (Stevenson's basal medium supplemented with D-sorbitol and neomycin sulfate), SM2 (Stevenson's basal medium supplemented with D-melezitose and neomycin sulfate), and SM3 (Gauze's medium supplemented with nalidixic acid and novobiocin); all three media contained antifungal antibiotics. Inoculated plates were incubated at 28°C for up to 21 d; the appearance of crusty or leathery colonies covered with white or whitish-yellow aerial hyphae proved to be characteristic of *Amycolatopsis* strains. Representative isolates were found to have morphological and chemotaxonomic features consistent with their assignment to the genus *Amycolatopsis.* Tan and her colleagues generated a set of genus-specific oligonucleotides which were used for the rapid identification of putative *Amycolatopsis* strains recovered from the selective isolation plates.

Maintenance procedures

Amycolatopsis strains can be cultivated on glucose-yeast extract agar or modified Bennett's agar. After incubation at 28°C to allow abundant growth, cultures may be maintained at 4°C or room temperature for up to 6 months. Long-term preservation can be achieved by lyophilization or in 20% glycerol frozen at −20°C or −80°C.

Differentiation of the genus *Amycolatopsis* from other genera

The genus *Amycolatopsis* can be distinguished from other genera in the *Pseudonocardiaceae* family by using a combination of chemotaxonomic and morphological markers (see Table 228 in the treatment of the family *Pseudonocardiaceae*). *Amycolatopsis* strains can also be distinguished from related taxa by using the genus-specific primers AMY2 and ATOP (Tan et al., 2006b).

Taxonomic comments

The genus *Amycolatopsis* was proposed by Lechevalier et al. (1986) for actinomycetes that formed substrate hyphae that tended to fragment into squarish elements, and aerial hyphae which, when formed, were either sterile or fragmented into chains of squarish to oval bodies or spore-like structures. The organisms had a wall chemotype IV (*meso*-diaminopimelic acid, arabinose, and galactose), a type II phospholipid pattern (PE with or without PME), and MK-9(H_2,H_4) as predominant isoprenologues, but lacked mycolic acids.

The founder members of the genus, *Amycolatopsis orientalis* (comprising *Amycolatopsis orientalis* subsp. *orientalis* and *Amycolatopsis orientalis* subsp. *lurida*), *Amycolatopsis mediterranei*, *Amycolatopsis rugosa*, and *Amycolatopsis sulphurea* were formally members of other taxa, notably the genera *Nocardia* and *Streptomyces.* The type species, *Amycolatopsis orientalis*, had been classified as *Actinomyces orientalis* (Krasil'nikov, 1981), *Nocardia orientalis* (Pridham, 1970), *Proactinomyces orientalis* (Rautenstein et al., 1975), and *Streptomyces orientalis* (Pittenger and Brigham, 1956). Similarly, *Amycolatopsis mediterranei* had previously been known as *Nocardia mediterranei* (Thiemann et al., 1969) and "*Streptomyces mediterranei*" (Margalith and Beretta, 1960). "*Nocardia lurida"* (Grundy et al., 1957), *Nocardia rugosa* (di Marco and Spalla, 1957), and "*Nocardia sulphurea*" (Oliver and Sinclair, 1964) were transferred to the genus *Amycolatopsis* as *Amycolatopsis orientalis* subsp. *lurida*, *Amycolatopsis rugosa*, and *Amycolatopsis sulphurea*, respectively.

The valid publication of *Amycolatopsis orientalis* subsp. *lurida* (*ex* Grundy et al. (1957) Lechevalier et al. (1986) automatically created the name *Amycolatopsis orientalis* subsp. *orientalis* (Pittenger and Brigham, 1956) Lechevalier et al. (1986) according to Rule 46 of the Bacteriological Code (Howey et al., 1990). However, the elevation of *Amycolatopsis orientalis* subsp. *lurida* to full species status automatically meant that the name *Amycolatopsis orientalis* subsp. *orientalis* reverted to the earlier name, *Amycolatopsis orientalis* (Pittenger and Brigham, 1956) Lechevalier et al. (1986), according to Rule 40d (formerly Rule 46) of the Bacteriological Code.

The taxonomic positions of *Amycolatopsis mediterranei*, *Amycolatopsis orientalis*, and *Amycolatopsis sulphurea* were underpinned by molecular systematic data (Embley et al., 1988a; Warwick et al., 1994), but the remaining species, *Amycolatopsis rugosa*, was subsequently reclassified as *Prauserella rugosa* gen. nov., sp. nov. (Kim and Goodfellow, 1999). Similarly, *Amycolatopsis orientalis* subsp. *lurida* was found to merit species status as *Amycolatopsis lurida* (Stackebrandt et al., 2004). Several other taxa were soon assigned to the genus, notably *Amycolatopsis coloradensis* Labeda (1995), *Amycolatopsis azurea* Henssen et al. (1987), and *Amycolatopsis fastidiosa* Henssen et al. (1987); these taxa previously had been classified as *Streptomyces candidis* (Kunstmann et al., 1968), *Pseudonocardia azurea* (Ōmura et al., 1979), and *Amycolatopsis fastidiosa* (Henssen et al., 1987), respectively. Another organism, *Amycolatopsis methanolica* de Boer et al. (1990) had formally been a member of the genus *Nocardia* (Hazeu et al., 1983) and, prior to that, of the genus *Streptomyces* (Kato et al., 1977).

The species *Amycolatopsis fastidiosa* was proposed by Henssen et al. (1987), based on chemotaxonomic and morphological properties, for a strain initially described as "*Pseudonocardia fastidiosa*" by Celmer et al. (1977) in a US patent. However, it has become increasingly clear from 16S rRNA gene sequence and *gyrB* sequence analysis, and DNA–DNA relatedness data mentioned earlier, that the strain is misplaced in the genus *Amycolatopsis.* It has also been noted that the strain did not give an amplification product using *Amycolatopsis*-specific oligonucleotide primers (Tan et al., 2006b). The organism has recently been transferred to the genus *Actinokineospora* as *Actinokineospora fastidiosa* comb. nov. following a careful evaluation of its chemotaxonomic, morphological, and physiological properties

and of its position in the order *Pseudonocardiales* (formerly suborder *Pseudonocardineae*) 16S rRNA gene tree (Labeda et al., 2010b).

Differentiation of the species of the genus *Amycolatopsis*

Amycolatopsis species can be distinguished using a combination of 16S rRNA gene sequence (Figure 291), DNA: DNA relatedness (Table 236) and phenotypic (Table 237) data, although a common set of phenotypic tests has not been used in the description of all species. Some *Amycolatopsis* species have been differentiated using MALDI-TOF MS spectra (Groth et al., 2007) and on the basis of fatty acid (Ding et al., 2007; Lee, 2006; Mertz and Yao, 1993) and ribotype (Wink et al., 2003b, 2004) patterns.

List of species of the genus *Amycolatopsis*

1. **Amycolatopsis orientalis** (Pittenger and Brigham 1956) Lechevalier, Prauser, Labeda and Ruan 1986, 35[VP] (Basonym: *Nocardia orientalis* Pridham and Lyons 1969, 183; "*Streptomyces orientalis*" Pittenger and Brigham 1956, 642.)

or.i.en.tal′is. L. fem. adj. *orientalis* of the orient.

Forms an extensive branched substrate mycelium which appears slightly zig-zag in places. When produced, the aerial mycelium differentiates into cylindrical, occasionally ovoid spores which are carried in straight to flexuous chains. Blue colored colonies and a light brown diffusible pigment are formed on modified Bennett's agar. Grows at 10–42°C, but not at 45°C.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, esterase (C4), and esterase lipase (C8), but negative for cystine arylamidase, α-fucosidase, α- and β-galactosidases, α- and β-glucosidases, β-glucuronidase, α-mannosidase, trypsin, and valine arylamidase (API ZYM tests). Positive for β-galactosidase, but not for arginine dehydrolase or lysine and ornithine decarboxylases (API 20E tests). Acetoin-positive, but indole-negative. Arbutin is hydrolyzed, but does not produce H_2S.

Elastin, Tween 40, uric acid, and xylan are degraded, but not adenine. Acid is not produced from either dulcitol or methyl β-D-xyloside. Acetate, citrate, malate, propionate, pyruvate, and succinate are used as sole carbon sources, but not benzoate, mucate, oxalate, or tartrate.

Resistant (μg/ml) to gentamicin sulfate (5), neomycin sulfate (8), novobiocin (10), penicillin G (20), polymyxin B (50), rifampin (10), streptomycin sulfate (16), tobramycin sulfate (8), and vancomycin hydrochloride (0.25), but sensitive to lysozyme. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{15:0}$ iso (15.2%), $C_{16:0}$ iso (23.8%), $C_{17:0}$ anteiso (13.7%), and $C_{17:0}$ (12.6%), and smaller proportions (<10%) of $C_{14:0}$ iso (4.3%), $C_{15:0}$ anteiso (11%), $C_{15:1}$ (1.3%), $C_{15:0}$ (7.2%), $C_{16:1}$ (3.5%), $C_{16:0}$ (8.6%), $C_{17:0}$ iso (1.5%), $C_{17:1}$ (1.2%), $C_{18:1}$ iso (1.5%), and $C_{18:0}$ (3.0%). Mycolic acids are absent. The polar lipid pattern contains PE as the diagnostic component. The predominant menaquinones are MK-9(H_2,H_4).

Source: isolated from soil, vegetable matter, and clinical specimens.

DNA G+C content (mol%): 66 (T_m).

Type strain: ATCC 19795, CIP 107113, DSM 40040, IFO (now NRBC) 12806, IMSNU 20058, JCM 4235, JCM 4600, NRRL 2450, UNIQEM 181, VKM Ac-866.

Sequence accession nos: AJ400711 (16S rRNA gene); EU822906 (*gyrB*).

2. **Amycolatopsis alba** Mertz and Yao 1993, 719[VP]

al′ba. L. fem. adj. *alba* white, referring to the white aerial hyphae.

Forms a yellowish-brown substrate mycelium and a white aerial mycelium on Bennett's, glycerol-asparagine, tomato paste-oatmeal, and yeast extract-glucose agars. A light brown soluble pigment is produced on Emerson's and yeast extract-malt extract agars. Cylindrical, smooth spores are formed with a typical cobweb morphology. Grows between 15 and 37°C, but not at 10 or 45°C.

Arbutin is hydrolyzed and H_2S is produced. Elastin, Tween 40, uric acid, and xylan are degraded.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, cystine arylamidase, esterase (C4), esterase lipase (C8), β-galactosidase, α-glucosidase, β-glucuronidase, leucine arylamidase, α-mannosidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine phosphatase, but negative for α-fucosidase, α-galactosidase, and lipase C14 (API ZYM tests). Positive for arginine dihydrolase, β-galactosidase, and lysine and ornithine decarboxylases (API 20E tests).

Acid is produced from ribose, but not from cellulose, dulcitol, ethanol, glycogen, inulin, or xylitol. Acetate, butyrate, formate, lactate, malate, propionate, pyruvate, and succinate are used as sole carbon sources, but not oxalate, mucate, or tartrate.

Resistant (μg/ml, unless otherwise indicated) to bacitracin (10 U), kanamycin (30), nalidixic acid (30), neomycin (30), oleandomycin (15), rifampin (5), streptomycin (10), sulfonamide (200), and tetracycline (30), but sensitive to cephalothin (30), gentamicin (10), lincomycin (2), penicillin (10 U), streptomycin (10), tobramycin (10), and vancomycin (30). Grows in the presence of lysozyme. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The cellular fatty acid profile includes major proportions of $C_{15:0}$ iso (30.0%) and $C_{17:0}$ (18.6%), and smaller proportions (<10%) of $C_{14:0}$ iso (2.9%), $C_{15:0}$ anteiso (6.6%), $C_{15:0}$ (6.0%), $C_{16:0}$ iso (9.3%), $C_{16:0}$ iso (7.8%), $C_{17:0}$ iso (2.8%), $C_{17:0}$ anteiso (3.8%), and $C_{18:0}$ (1.5%). Mycolic acids are absent. PE is the diagnostic polar lipid. The predominant menaquinone is MK-9(H_4); also contains minor amounts of MK-8(H_4).

Source: isolated from soil.

[a]+, Positive; $+^{w}$, weakly positive; −, negative; v, variable; nr, not reported.

DNA G+C content (mol%): not determined.

Type strain: A83850, ATCC 51368, DSM 44262, NBRC 15602, JCM 10030, NRRL 18532.

Sequence accession nos: AF051340 (16S rRNA gene); EU822885 (*gyrB*).

3. **Amycolatopsis albidoflavus** Lee and Hah 2001, 649[VP]

al.bi.do.fla'vus. L. adj. *albidus* white; L. adj. *flavus* yellow; N.L. adj. *albidoflavus* whitish yellow.

Forms well developed aerial and vegetative mycelia that fragment into rod-shaped elements. The aerial mycelium is white and the substrate mycelium is orange yellow; a yellow soluble pigment is formed on modified Bennett's agar. Grows between 10 and 37°C, but not at 45°C.

Phosphatase-positive. Does not produce acid from L-sorbose or xylitol. Benzoate, citrate, lactate, oxalate, and propionate are used as sole carbon sources, but not mucate or tartrate. Grows in the presence of 7% (w/v) NaCl.

Resistant (μg/ml) to gentamicin sulfate (5), neomycin sulfate (8), novobiocin (10), penicillin G (20), polymyxin B (50), rifampin (10), streptomycin sulfate (16), tobramycin sulfate (8), and vancomycin hydrochloride (0.25). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Muramic acid is in the *N*-acetylated form. The cellular fatty acid profile includes major proportions of $C_{16:0}$ iso (26.1%), $C_{14:0}$ iso (9.8%), and $C_{16:0}$ (10.2%), and smaller proportions (<10%) of $C_{14:0}$ (1.1%), $C_{15:0}$ iso (8.7%), $C_{15:1}$ (2.3%), $C_{15:0}$ (5.8%), $C_{16:1}$ (4.0%), $C_{17:0}$ iso (1.6%), $C_{17:1}$ (4.4%), $C_{17:0}$ (7.8%), and $C_{18:0}$ (6.2%). The cellular polar lipid pattern includes PE and PI. The predominant menaquinone is MK-9(H_4).

Source: isolated from soil.

DNA G+C content (mol%): 68.5 (HPLC).

Type strain: ATCC 53205, DSM 44639, IMSNU 22139, JCM 11300, KCTC 9471, NBRC 100337, NRRL B-24149.

Sequence accession nos: AJ252832 (16S rRNA gene); EU822886 (*gyrB*).

4. **Amycolatopsis australiensis** Tan, Robinson, Lacey and Goodfellow 2006a, 2299[VP]

aus.tra.li.en'sis. N.L. fem. adj. *australiensis* pertaining to Australia, the source of the soil from which the first strains were isolated.

Forms an extensively branched substrate mycelium which fragments into squarish rod-shaped elements. Abundant, white aerial hyphae, a pale yellow substrate mycelium, and a medium yellow diffusible pigment are produced on modified Bennett's agar supplemented with mannitol and soybean flour. Melanin pigments are not formed on peptone-yeast extract-iron or tyrosine agars. Grows between 28 and 45°C, and from pH 5 to 7.

Tween 40 and uric acid are degraded. Acid is produced from arabitol, glycogen, and turanose, but not from dulcitol, D-ribose, or xylitol. Citrate, oxalate, and propionate are used as sole carbon sources, but not benzoate, lactate, or mucate (all at 0.1%, w/v).

Resistant (μg/ml) to gentamicin sulfate (5), neomycin sulfate (8), polymyxin B (50) and tobramycin sulfate (8), but sensitive to novobiocin (10), penicillin G (20), rifampin (10), and streptomycin sulfate (16). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Muramic acid is *N*-acetylated. Mycolic acids are not present. The polar lipid pattern includes DPG, PE, PG, PI, and PME. The predominant menaquinone is MK-9(H_4); also contains MK-8(H_2) (26%) and MK-9(H_8) (8%).

Source: isolated from arid soil collected from Western Australia.

DNA G+C content (mol%): not determined.

Type strain: GY048, DSM 44671, JCM 15587, NCIMB 14142.

Sequence accession nos: AY129753 (16S rRNA gene); EU822887 (*gyrB*).

5. **Amycolatopsis azurea** (Ōmura, Tanaka, Tanaka, Spiri-Nakagawa, Oiwa, Takahashi, Matsuyama and Iwai 1983) Henssen, Kothe and Kroppenstedt 1987, 294[VP] (Basonym: *Pseudonocardia azurea* Ōmura, Tanaka, Tanaka, Spiri-Nakagawa, Oiwa, Takahashi, Matsuyama and Iwai 1983, 673.)

a.zu're.a. N.L. fem. adj. *azurea* azure blue, referring to the color of aerial mycelium.

Forms irregularly branched substrate hyphae which tend to be zig-zag-shaped. The aerial mycelium is usually white, but is blue on sucrose-nitrate and tyrosine agars, and pink on glucose-peptone agar. The substrate mycelium is brownish black and the aerial mycelium is light gray on modified Bennett's agar. Blue soluble pigments are produced on glucose-nitrate and starch-yeast extract agars. Aerial spores are smooth and cylindrical (0.4–1.1 × 3.7 μm). Grows between 10 and 36°C, but not at 37 or 45°C.

Positive for *N*-acetyl-β-glucosamidase, α-chymotrypsin, esterase lipase (C8), β-galactosidase, α- and β-glucosidases, leucine arylamidase, naphthol-AS-BI-phosphohydrolase, and trypsin, but negative for alkaline phosphatase, cystine arylamidase, esterase (C4), α-fucosidase, α-galactosidase, β-glucuronidase, lipase (C14), α-mannosidase, and valine arylamidase (API ZYM tests). Positive for arginine dihydrolase, β-galactosidase, and lysine and ornithine decarboxylases (API 20E tests). Acetoin-positive, but indole-negative. Arbutin is hydrolyzed, but does not produce H_2S. Elastin, Tween 40, uric acid, and xylan are degraded. Citrate, oxalate, and propionate are used as sole carbon sources, but not benzoate, lactate, or mucate (all at 0.1%, w/v). Grows in the presence of 7% (w/v) NaCl.

Resistant (μg/ml) to gentamicin sulfate (5), kanamycin (30), nalidixic acid (30), neomycin sulfate (8), penicillin G (20), polymyxin B (50), rifampin (10), streptomycin sulfate (16), sulfonamide (200), tobramycin sulfate (8), and vancomycin hydrochloride (30). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{15:0}$ iso (30.0%), $C_{17:0}$ (11.8%), and $C_{17:0}$ (25.7%), and smaller proportions (>10) of $C_{15:0}$ anteiso (3.9%), $C_{15:0}$ (6.5%), $C_{16:0}$ iso (2.9%), $C_{16:1}$ (8.8%), $C_{16:0}$ (5.7%), $C_{17:0}$ iso (2.6%), and $C_{18:0}$ iso (2.1%). Mycolic acids are not present. The polar lipid pattern contains DPG, PE, PG, PI, and PIMs. The predominant menaquinone is MK-9(H_4); also contains MK-8(H_4) and MK-9(H_4).

Source: isolated from soil.

DNA G+C content (mol%): 66 (T_m).

Type strain: AM-3696, ATCC 51273, DSM 43854, FERM-P 4738, IFO (now NRBC) 14573, IMSNU 20053, JCM 3275, NRRL 11412, VKM Ac-1418.

Sequence accession nos: AJ400709 (16S rRNA gene); EU822888 (*gyrB*).

6. **Amycolatopsis balhimycina** Wink, Kroppenstedt, Ganguli, Nadkarni, Schumann, Seibert and Stackebrandt 2003a, 935[VP] (Effective publication: Wink, Kroppenstedt, Ganguli, Nadkarni, Schumann, Seibert and Stackebrandt 2003b, 44.)

bal.hi.my′ci.na. N.L. n. *balhimycinum* balhimycin (an antibiotic produced by the organism); L. fem. suff. *-ina* suffix used with the sense of belonging to; N.L. fem. adj. *balhimycina* pertaining to balhimycin.

Forms a chrome yellow substrate mycelium on glycerol-asparagine, inorganic salts-starch, oatmeal, peptone-yeast extract, tyrosine, and yeast-extract-malt extract agars (ISP media 2–7); soluble pigments are not formed on any of these media. Fragmentation of the substrate mycelium and white aerial hyphae into more or less irregular arthrospores is only seen on oatmeal agar.

Positive for alkaline phosphatase, *N*-acetyl-β-glucosamidase, α-chymotrypsin, cystine arylamidase, α-fucosidase, α- and β-galactosidases, α-glucosidase, leucine arylamidase, lipase (C14), naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase, but negative for β-glucuronidase and α-mannosidase (API ZYM tests). Produces H_2S. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{16:0}$ iso (36.0%), and smaller proportions (<10%) of $C_{15:0}$ (5.3%), $C_{16:0}$ (2.0%), $C_{17:0}$ (2.2%), $C_{15:1}$ (5.1%), $C_{14:0}$ iso (3.8%), $C_{15:0}$ iso (5.7%), C_{161} (7.3%), $C_{17:0}$ iso (1.2%), $C_{15:0}$ anteiso (1.5%), $C_{17:0}$ anteiso (4.1%), $C_{16:1}$ *cis*9 (4.0%), $C_{17:1}$ *cis*9 (7.6%), $C_{16:0}$ 10-methyl (2.4%), $C_{17:0}$ 10-methyl (3.2%), 2-hydroxy-$C_{16:0}$ (7.7%), and $C_{17:0}$ anteiso 2-OH (0.7%). Mycolic acids are absent. The polar lipid pattern contains DPG, HPE, PE, PG, and PI. The predominant menaquinone is MK-9(H_4).

Source: isolated from a soil sample collected in India.

DNA G+C content (mol%): not determined.

Type strain: FH 1894, DSM 44591, JCM 12668, NRRL B-24207.

Sequence accession nos: AJ508239 (16S rRNA gene); EU822889 (*gyrB*).

7. **Amycolatopsis benzoatilytica** Majumdar, Prabhagaran, Shivaji and Lal 2006, 202[VP]

ben.zo.a.ti.ly′ti.ca. N.L. n. *benzoas -atis* benzoate; N.L. adj. *lyticus-a-um* (from Gr. adj. *lutikos-ê-on*) dissolving; N.L. fem. adj. *benzoatilytica* benzoate-degrading.

Forms cream-colored, irregularly shaped, rough, flat colonies with undulating margins. The substrate mycelium tends to fragment in liquid medium. Grows between 10 and 37°C, and from pH 5 to 10.

Tween 80 is degraded and *m*-hydroxybenzoate is metabolized. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{14:0}$ iso (11.3%), $C_{15:0}$ (14.7%), $C_{15:1}$ ω6*c* (12.8%), $C_{16:0}$ iso (12.8%), $C_{17:0}$ (11.3%), and $C_{17:1}$ ω8*c* (11.3%), and smaller proportions (<10%) of $C_{15:0}$ iso (6.8%), $C_{15:0}$ anteiso (3%), $C_{16:0}$ (5.2%), and $C_{15:0}$ 2-OH (1%). The polar lipid pattern contains DPG, PE, PG, PI, and PME. The predominant menaquinone is MK-9(H_4).

Source: isolated from a patient with submandibular mycetoma.

DNA G+C content (mol%): not determined.

Type strain: AK 16/65, ATCC 55165, DSM 43387, IMRU 1389, JCM 13851.

Sequence accession no. (16S rRNA gene): AY957506.

Additional comments: the strain was initially identified as *Nocardia brasiliensis* (Scharfen, 1971) and reclassified as *Nocardia orientalis* by Gordon et al. (1978).

8. **Amycolatopsis coloradensis** Labeda 1995, 126[VP]

co.lo.rad.en′sis. N.L. fem. adj. *coloradensis* of Colorado, the source of the soil sample from which the type strain was isolated.

Forms a yellow to orange substrate mycelium. When formed, the aerial mycelium is sparse and white to olive buff. Aerial hyphae differentiate into chains of straight to flexuous cylindrical to ovoid spores. An orange yellow soluble pigment is produced on most growth media, including modified Bennett's agar. Grows at 10 to 37°C, but not at 45°C.

Arbutin is not hydrolyzed nor is H_2S produced. Elastin, Tween 40, and xylan are degraded, but not uric acid. Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, esterase (C8), leucine arylamidase, lipase (C14), and trypsin, but negative for cystine arylamidase, esterase (C4), α-fucosidase, α- and β-galactosidases, α- and β-glucosidases, β-glucuronidase, α-mannosidase, naphthol-AS-BI-phosphohydrolase, and valine arylamidase (API ZYM tests). Positive for arginine dihydrolase, β-galactosidase, and lysine and ornithine decarboxylases, but not for β-galactosidase (API 20E tests). Acetate, malate, propionate, pyruvate, and succinate are used as sole carbon sources, but not benzoate, citrate, mucate, oxalate, or tartrate.

Resistant (μg/ml) to gentamicin sulfate (5), neomycin sulfate (8), polymyxin B (50), streptomycin sulfate (16), tobramycin sulfate (8), and vancomycin hydrochloride (0.25). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{15:0}$ (14.6%), $C_{15:1}$ ω6*c* (12.8%), $C_{16:0}$ iso (25) and $C_{17:0}$ (11.3%), and smaller proportions of $C_{14:0}$ iso (0.5%), $C_{15:0}$ iso (6.8%), $C_{15:0}$ anteiso (3.0%), $C_{16:0}$ (5.2%), $C_{16:1}$ iso H (0.2%), $C_{17:0}$ iso (0.4%), $C_{17:0}$ anteiso (0.8%), and $C_{18:0}$ (0.4%). Mycolic acids are absent. The cellular polar lipid pattern contains PE as the diagnostic nitrogen-containing component. The predominant menaquinone is MK-9(H_2,H_4).

Source: isolated from a soil sample collected in Colorado.

DNA G+C content (mol%): 66 (T_m).

Type strain: ATCC 53629, DSM 44225, IFO (now NRBC) 15804, JCM 9869, NRRL 3218, VKM Ac-1732.

Sequence accession nos: AF051341 (16S rRNA gene); EU822890 (*gyrB*).

9. **Amycolatopsis decaplanina** Wink, Gandhi, Kroppenstedt, Seibert, Sträubler, Schumann and Stackebrandt 2004, 237[VP]

de.ca.pla'ni.na. N.L. neut. n. *decaplaninum* decaplanin; L. fem. suff. *-ina* related to; N.L. fem. adj. *decaplanina* related to decaplanin, an antibiotic produced by the organism.

Honey yellow substrate mycelium is formed on glycerol-asparagine, inorganic salts-starch, oatmeal, peptone-yeast extract-iron, tyrosine, tryptone-yeast extract, and yeast extract-malt extract agars (ISP media 1–7). Only produces an aerial mycelium on oatmeal agar and a soluble red pigment on tyrosine agar. Melanin pigments are not formed. Regular shaped to globose and smooth-surfaced pseudosporangia are produced, but spores are not seen either inside or outside these bodies.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, β-galactosidase, α- and β-glucosidases, leucine arylamidase, α-mannosidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase, but negative for cystine arylamidase, esterase (4), esterase lipase (C8), α-fucosidase, α-galactosidase, β-glucuronidase, and lipase (C14) (API ZYM tests). Positive for β-galactosidase, but not for arginine dihydrolase or lysine and ornithine decarboxylases (API 20E tests). Produces acetone, but not indole. Arbutin is hydrolyzed, but H_2S is not produced. Elastin and Tween 40 are degraded, but not uric acid or xylan. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{15:0}$ iso (22.5%), $C_{17:0}$ (11.4%), and $C_{16:0}$ iso (10.3%), and smaller proportions (<10%) of $C_{14:0}$ iso (6.4%), $C_{15:0}$ anteiso (9.4%), $C_{15:0}$ iso 2-OH (8.7%), $C_{15:0}$ (7.6%), $C_{17:1}$ (5.8%), $C_{16:0}$ (3.3%), $C_{15:1}$ (2.1%), $C_{17:0}$ iso (1.7%), $C_{17:0}$ anteiso (3.4%), $C_{16:0}$ iso 2-OH (2.8%), $C_{15:0}$ anteiso 2-OH (1.9%), $C_{17:0}$ 2-OH (1.5%) and $C_{17:0}$ 10-methyl iso (1.2%). The polar lipid pattern contains DPG, HPE, PE, PG, PI, and PIMs. The predominant menaquinones are MK-8(H_4) and MK-9(H_4).

Source: isolated from a soil sample collected in India.

DNA G+C content (mol%): not determined.

Type strain: FH 1845, DSM 44594, JCM 12669, NRRL B-24209.

Sequence accession nos: AJ508237 (16S rRNA gene); EU822891 (*gyrB*).

Additional comments: the type strain of *Amycolatopsis decaplanina* has a ribotype pattern which distinguishes it from phylogenetically related *Amycolatopsis* strains (Wink et al., 2004).

10. **Amycolatopsis echigonensis** Ding, Hirose and Yokota 2007, 1750[VP]

e.chi.go.nen'sis. N.L. fem. adj. *echigonensis* referring to Echigo, the old name of Niigata Prefecture, Japan, the source of the type strain.

The substrate mycelium is light yellow and the aerial mycelium white. Grows between 5 and 45°C, and optimally at 30°C, and from pH 6 to 11, optimally at pH 9.0.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, cystine arylamidase, esterase (C4), esterase lipase (C8), α- and β-galactosidases, α-glucosidase, β-glucuronidase, leucine arylamidase, α-mannosidase, trypsin, and valine arylamidase, but negative for α-fucosidase, β-glucosidase, and lipase (C14) (API ZYM tests). Grows in the presence of 7% (w/v) NaCl. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{15:0}$ anteiso (16.7%) and $C_{16:0}$ iso (31.9%), and smaller proportions (<10%) of $C_{14:0}$ iso, (6.5%), $C_{14:0}$ (0.4%), $C_{15:0}$ iso (7.0%), $C_{15:0}$ (5.2%), $C_{15:1}$ ω6*c* (3.6%), $C_{16:0}$ (2.5%), $C_{16:1}$ iso OH (1.3%), $C_{17:0}$ iso (1.1%), $C_{17:}$ (6.9%), $C_{17:0}$ (3.4%), $C_{17:1}$ ω6*c* (5.6%), and $C_{17:1}$ ω8*c* (2.4%). Mycolic acids are absent. The predominant menaquinone is MK-9(H_4).

Source: isolated from filtration material made from volcanic soil, Niigata, Japan.

DNA G+C content (mol%): 72.4 (HPLC).

Type strain: LC2, CCTCC AB206019, IAM 15387, JCM 21831.

Sequence accession nos: AB248535 (16S rRNA gene); EU822892 (*gyrB*).

11. **Amycolatopsis eurytherma** Kim, Sahin, Tan, Zakrzewska-Czerwinska and Goodfellow 2002a, 893[VP]

eur.y.ther'ma. Gr. adj. *eurus* wide, broad; Gr. adj. *thermos* hot; N.L. fem. adj. *eurytherma* grows over a wide temperature range.

Extensively branched substrate hyphae fragment into squarish, rod-like elements (approx. 0.4–0.5 × 0.7–1.6 µm). Forms a yellow substrate mycelium on modified Bennett's and glucose-yeast extract agars, but distinct pigments are not evident on Czapek-Dox, glycerol-asparagine, or oatmeal agars; diffusible pigments are not formed on any of these media. Melanin pigments are not produced on peptone-yeast extract-iron or tyrosine agars. Aerial mycelium is white, sparse, and sterile. Grows from 25 to 55°C, but not at 10 or 60°C and from pH 6 to 9.

Negative for β-galactosidase and *N*-acetyl-β-glucosamidase. Elastin and xylan are decomposed, but not chitin or guanine. Grows on adonitol, L-arabinose, cellobiose, fructose, galactose, *myo*-inositol, lactose, mannitol, mannose, melezitose, melibiose, rhamnose, ribose, sorbitol, starch, sucrose, trehalose, turanose, xylitol, and xylose as sole carbon sources, but not on raffinose (all at 1%, w/v).

Resistant (µg/ml) to ampicillin (32), bacitracin (16), carbenicillin (12), cefoxitin (32), cephaloridine (128), cephradine (32), doxycyline hydrochloride (4), ethionamide (16), fusidic acid (4), gentamicin sulfate (32), gramicidin (8), isoniazid (16), lincomycin hydrochloride (128), lividomycin A (8), nalidixic acid (32), neomycin sulfate (8), novobiocin (4), oleandomycin phosphate (128), penicillin G (15 IU), polymyxin B (50), rifampin (64), spiramycin (10), streptomycin sulfate (64), tetracycline hydrochloride (32), tobramycin sulfate (8), vancomycin hydrochloride (64), and viomycin sulfate (20), but sensitive to amikacin (4), bacitracin (32), doxycyclin (6), fusidic acid (8), gentamicin (64), lividomycin A (16), neomycin sulfate (32),

novobiocin (16), streptomycin sulfate (64), ticarcillin (16), and tyrothricin (16). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{16:0}$ iso (46%) and $C_{16:0}$ (23%), and smaller proportions (<10%) of $C_{15:0}$ iso, (4%), $C_{17:0}$ iso (6%), $C_{17:0}$ anteiso (9%), $C_{17:0}$ (3%), and $C_{16:0}$ (3%). Mycolic acids are absent. The polar lipid pattern contains DPG, PE, PG, PI, PI dimannoside, and PME. The predominant isoprenologue is MK-9(H_4).

Source: isolated from arid and scrubland soil collected in Madurai, India, and Van, Turkey, respectively.

DNA G+C content (mol%): 72.2–74.0 (HPLC).

Type strain: NT202, DSM 44348, JCM 12071, NBRC 100338, NCIMB 13795.

Sequence accession nos: AJ000285 (16S rRNA gene); EU822893 (*gyrB*).

12. **Amycolatopsis halotolerans** Lee 2006, 552[VP]

ha.lo.to′le.rans. Gr. n. *hals halos* salt; L. part. adj. *tolerans* tolerating, enduring; N.L. part. adj. *halotolerans* salt-tolerating.

Forms well-developed, branched aerial and substrate mycelia that fragment into rod-shaped elements. The substrate mycelium is brown and the aerial mycelium is grayish white on yeast extract-malt extract agar (ISP medium 2). Grows between 10 and 37°C, but not at or above 45°C.

Does not produce acid from D-arabinose, dulcitol, methyl α-D-mannoside, sorbose, or xylitol. Growth occurs in the presence of 7%, but not 10% (w/v) NaCl. Additional phenotypic properties are shown in Table 238.

Whole-organism methanolyzates are rich in arabinose and galactose. Muramic acid moieties are *N*-acetylated. Cellular fatty acids contain major proportions of $C_{15:0}$ iso (13.0%), $C_{16:0}$ (16.2%), $C_{16:0}$ iso (17.6%), $C_{17:0}$ (14.5%), and $C_{18:0}$ (13.2%), and smaller proportions (<10%) of $C_{15:0}$ (3.7%), $C_{17:0}$ iso, (5.0%), $C_{15:0}$ anteiso (3.2%), $C_{17:0}$ anteiso, (3.1%), $C_{14:0}$ 2-OH (0.8%), and $C_{15:0}$ iso 3-OH (5.2%). Mycolic acids are absent. The polar lipid pattern contains DPG, PE, PG, and PI. The predominant menaquinone is MK-9(H_4); minor amounts of MK-9(H_6) and MK-9(H_8) are also present.

Source: isolated from soil collected inside a natural cave on Jeju Island, Republic of Korea.

DNA G+C content (mol%): 72.5 (HPLC).

Type strain: N4-6, DSM 45041, JCM 13279, NRRL B-24428.

Sequence accession nos: DQ000196 (16S rRNA gene); EU822895 (*gyrB*).

13. **Amycolatopsis japonica** corrig. Goodfellow, Brown, Cai, Chun and Collins 1997b, 915[VP] (Effective publication: Goodfellow, Brown, Cai, Chun, Collins 1997a, 81.)

ja.po′ni.ca. N.L. fem. adj. *japonica* pertaining to Japan.

Forms substrate and aerial mycelia which fragment into squarish elements. A yellow brown substrate mycelium, a white aerial mycelium and a dark olive brown diffusible pigment are formed on modified Bennett's agar. Grows between 10 and 45°C.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, cystine arylamidase, esterase (C4), esterase lipase (C8), α-fucosidase, α- and β-galactosidases, α- and β-glucosidases, leucine arylamidase, lipase (C14), α-mannosidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase, but negative for β-glucuronidase (API ZYM tests). Positive for β-galactosidase, arginine dihydrolase, and lysine and ornithine decarboxylases (API 20E tests). Acetoin-positive, but indole- and lecithanase-negative. Produces lipolytic enzymes. Arbutin is hydrolyzed, but not hippurate. H_2S is not produced.

DNA, elastin, RNA, Tweens 20, 40, 60 and 80, uric acid, and xylan are degraded, but not adenine, chitin, or pectin. Adonitol, L-arabinose, fructose, galactose, *myo*-inositol, lactose, mannitol, melibiose, raffinose, rhamnose, salicin, sucrose, and xylose are used as sole carbon sources, but not dextran, melezitose, or xylitol (all at 0.1%, w/v). Similarly, citrate, propionate, and pyruvate are used as sole carbon sources (all at 1.0%, w/v). DL-α-Amino-*n*-butyric acid, L-cysteine, L-histidine, L-hydroxyproline, L-phenylalanine, potassium nitrate, and L-threonine are used as sole carbon and nitrogen sources, but not L-valine. Grows in the presence of crystal violet (0.0001%, w/v) and potassium tellurite (0.001%, w/v), but is inhibited by phenol (0.1%, w/v), sodium azide (0.01%, w/v), sodium chloride (7%, w/v), and thallous acetate (0.001%, w/v).

Resistant (μg/ml) to gentamicin sulfate (5), neomycin sulfate (8), novobiocin (10), penicillin G (20), polymyxin B (50), rifampin (10), streptomycin sulfate (16), tobramycin sulfate (8), and vancomycin hydrochloride (0.25), but sensitive to neomycin sulfate (50), triacyl oleandomycin (100) and rifampin (50). Additional phenotypic properties are shown in Table 238.

Whole-organism methanolyzates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{16:0}$ iso (41.4%), $C_{16:0}$ (13.2%), and $C_{15:0}$ iso (13.5%). Mycolic acids are absent. The polar lipid pattern contains DPG, PE, PG, PI, and PIMs. The predominant menaquinone is MK-9(H_4).

Source: isolated from soil.

DNA G+C content (mol%): 69.5 (T_m).

Type strain: MG417-CF17, CIP 106801, DSM 44213, JCM 10140, NRRL B-24138.

Sequence accession nos: AJ508236 (16S rRNA gene); EU822896 (*gyrB*).

Additional comments: the original spelling, *Amycolatopsis japonicum* (*sic*) was corrected at validation in line with Rule 61 of the Bacteriological Code (Associate Editor, 1997).

14. **Amycolatopsis jejuensis** Lee 2006, 552[VP]

je.ju.en′sis. N.L. fem. adj. *jejuensis* of Jeju Island, Republic of Korea.

Forms well-developed, branched aerial and substrate mycelia that fragment into rod-shaped elements. The substrate mycelium is yellowish brown and the aerial mycelium is white on yeast extract-malt extract agar (ISP medium 2); does not produce soluble pigments. Grows between 10 and 30°C.

Acid is produced from D-arabinose, but not from dextran, dulcitol, inulin, methyl α-D-mannoside, ribose, sorbose, L-xylose, or D-xylitol. Grows in the presence of 2%,

but not 3% (w/v) NaCl. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Muramic acid moieties are *N*-acetylated. Cellular fatty acids profiles contain major proportions of $C_{15:0}$ iso (14.3%), $C_{16:0}$ (20.2%), $C_{16:0}$ iso (14.6%), and $C_{18:0}$ (17.5%), and minor proportions (<10%) of $C_{14:0}$ (1.2%), $C_{16:1}$ (0.9%), $C_{14:0}$ iso (2.2%), $C_{15:0}$ (2.6%), $C_{17:0}$ (4.8%), $C_{17:0}$ iso (5.0%), $C_{15:0}$ anteiso (3.2%), $C_{17:0}$ anteiso (3.5%), $C_{20:0}$ (1.1%), $C_{14:0}$ 2-OH (0.6%), and $C_{15:0}$ iso 3-OH (7.6%). Mycolic acids are absent. The polar lipid pattern contains DPG, PE, PG, PI, and PIMs. The predominant menaquinone is MK-9(H_4).

Source: isolated from dried bat dung from a natural cave on Jeju Island, Republic of Korea.

DNA G+C content (mol%): 71.7 (HPLC).

Type strain: N7-3, DSM 45042, JCM 13280, NRRL B-24427.

Sequence accession nos: DQ000200 (16S rRNA gene); EU822897 (*gyrB*).

15. **Amycolatopsis kentuckyensis** Labeda, Donahue, Williams, Sells and Henton 2003, 1602[VP]

ken.tuc.ky.en′sis. N.L. fem. adj. *kentuckyensis* from Kentucky, named after the place of origin, the state of Kentucky, USA.

Forms a well-developed, yellow-orange to brownish-orange substrate mycelium and a light orangish-white to grayish orange-white aerial mycelium on most media. A faint brownish soluble pigment is produced on some media. Grows from 15 to 42°C.

Hippurate is hydrolyzed. Does not degrade adenine. Acid is produced from dulcitol, but not from methyl β-xyloside. Acetate and citrate are used as sole carbon sources; benzoate, lactate, malate, mucate, oxalate, propionate, succinate, and DL-tartrate are used weakly, if at all. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acids profiles contain major proportions of $C_{15:0}$ iso (14.2%), $C_{16:0}$ iso (17.2%) and $C_{17:1}$ *cis*9 (10.1%), and smaller proportions (<10%) of $C_{14:0}$ iso (2.2%), $C_{15:0}$ anteiso (3.3%), $C_{15:1}$ (1.0%), $C_{15:0}$ (5.1%), $C_{16:1}$ *cis*9 (2.3%), $C_{16:0}$ (3.0%), $C_{16:0}$ 9-methyl (3.3%), $C_{17:0}$ iso (2.4%), $C_{17:0}$ anteiso (6.6%), $C_{16:0}$ 2-OH (2.9%), $C_{17:0}$ (6.2%), and $C_{17:0}$ 10-methyl (5.3%). The major phospholipid is PE; smaller amounts of PME are also present. The predominant menaquinones are MK-9(H_2) and MK-9(H_4).

Source: isolated from equine placentas.

DNA G+C content (mol%): not determined.

Type strain: LDDC 9447-99, DSM 44652, JCM 12570, NRRL B-24129.

Sequence accession no. (16S rRNA gene): AY183357.

16. **Amycolatopsis keratiniphila** Al-Musallam, Al-Zarban, Fasasi, Kroppenstedt and Stackebrandt 2003, 872[VP]

ke.ra.ti.ni′phi.la. N.L. n. *keratinum* keratin; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *keratiniphila* keratin-loving, referring to the ability of the species to degrade keratin.

Additional comments: the type strain NRRL B-24117 was mistakenly cited as NRRL B24117 in Al-Musallam et al. (2003). The taxon was subsequently divided into two subspecies.

16a. **Amycolatopsis keratiniphila subsp. keratiniphila** Wink, Kroppenstedt, Ganguli, Nadkarni, Schumann, Seibert and Stackebrandt 2003a, 935[VP] (Effective publication: Wink, Kroppenstedt, Ganguli, Nadkarni, Schumann, Seibert and Stackebrandt 2003b, 44.) (*Amycolatopsis keratiniphila* Al-Musallam, Al-Zarban, Fasasi, Kroppenstedt and Stackebrandt 2003, 872)

Light gray aerial mycelium is formed; does not form a soluble pigment. Grows between 10 and 28°C.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, cystine arylamidase, esterase (C4), esterase lipase (C8), α- and β-galactosidases, α- and β-glucosidases, leucine arylamidase, lipase (C14), trypsin, and valine arylamidase, but negative for α-fucosidase, β-glucuronidase, α-mannosidase and naphthol-AS-BI-phosphohydrolase (API ZYM tests). Positive for arginine dehydrolase, β-galactosidase, and lysine and ornithine decarboxylases (API 20E tests). Acetoin-positive, but indole-negative. Arbutin is hydrolyzed, but does not produce H_2S. Elastin and Tween 40 are degraded, but not uric acid or xylan.

Resistant (filter paper discs soaked in μg/ml) to nalidixic acid (30), streptomycin (10), sulfonamide (200), and vancomycin (30), but sensitive to kanamycin (30). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The cellular fatty acid profile contains major proportions of $C_{16:0}$ iso (33.5%) and $C_{14:0}$ iso (13.9%), and smaller proportions (<10%) $C_{17:1}$ (9.9%), $C_{15:0}$ iso (8.0%), $C_{17:0}$ (7.6%), 2-hydroxy-$C_{16:0}$ iso (7.4%), $C_{15:0}$ (7.1%), $C_{16:1}$ (4.9%), $C_{16:0}$ (2.0%), $C_{15:0}$ anteiso, (1.9%), $C_{17:0}$ anteiso (1.3%), $C_{17:0}$ 10-methyl iso (1.0%), 2-hydroxy-$C_{15:0}$ anteiso (0.9%) and $C_{17:0}$ iso (0.8%). Mycolic acids are not formed. The polar lipid pattern contains DPG, HPE, PE, and PI. The predominant menaquinone is MK-9(H_4).

Source: isolated from agricultural soil in Kuwait using animal wool in bait.

DNA G+C content (mol%): not determined.

Type strain: D2, DSM 44409, JCM 12683, NRRL B-24117.

Sequence accession nos: AJ278496 (16S rRNA gene); EU822898 (*gyrB*).

16b. **Amycolatopsis keratiniphila subsp. nogabecina** Wink, Kroppenstedt, Ganguli, Nadkarni, Schumann, Seibert and Stackebrandt 2003a, 935[VP] (Effective publication: Wink, Kroppenstedt, Ganguli, Nadkarni Schumann, Seibert and Stackebrandt 2003b, 44.)

no.ga.be′ci.na. N.L. n. *nogabecinum* nogabecin (an antibiotic produced by the organism); L. fem. suff. *-ina* suffix used with sense of belonging to; N.L. fem. adj. *nogabecina* pertaining to nogabecin, an antibiotic produced by the organism.

The substrate mycelium is sand yellow on oatmeal, peptone-yeast extract-iron, and yeast extract-malt extract agars and beige on glycerol-asparagine, inorganic salts, and tyrosine agars; soluble pigments are not formed on any of these media. Aerial hyphae are not produced.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, cystine arylamidase, esterase

(C8), α- and β-galactosidases, α-glucosidase, leucine arylamidase, lipase (C14), α-mannosidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase, but negative for esterase (C4), α-fucosidase, and β-glucuronidase (API ZYM tests). Positive for arginine dihydrolase, β-galactosidase, and lysine and ornithine decarboxylases (API 20E tests) Arbutin is hydrolyzed and H_2S produced. Tween 40 is degraded, but not elastin, uric acid, or xylan.

Resistant (filter paper discs soaked in µg/ml) to nalidixic acid (30), streptomycin (10) and vancomycin, but is susceptible to kanamycin (30) and sulfonamide (200). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The fatty acid profile contains major proportions of $C_{16:0}$ iso (31.9%), $C_{14:0}$ iso (12.3%), and $C_{17:0}$ (10.9%), and smaller proportions of $C_{15:0}$ (9.1%), $C_{16:0}$ (2.2%), $C_{17:1}$ *cis*9 (3.8%), $C_{15:0}$ iso (9.8%), $C_{17:0}$ iso (0.9%), $C_{15:0}$ anteiso (2.0%), $C_{17:0}$ anteiso (1.8%), $C_{18:0}$ iso (0.4%), $C_{17:0}$ 10-methyl iso (2.1%), $C_{17:0}$ 10-methyl (0.3%), 2-hydroxy-$C_{15:0}$ iso (3.9%), 2-hydroxy-$C_{15:0}$ iso (0.9%), 2-hydroxy-$C_{16:0}$ iso (7.7%), and 2-hydroxy-$C_{17:0}$ anteiso (0.9%). Mycolic acids are absent. The polar lipid pattern contains DPG, HPE, PE, and PI. The predominant menaquinone is MK-9(H_4).

Source: isolated from a soil sample collected in India.

DNA G+C content (mol%): not determined.

Type strain: FH 1893, DSM 44586, JCM 12671, NRRL B-24206.

Sequence accession nos: AJ508238 (16S rRNA gene); EU822899 (*gyrB*).

17. **Amycolatopsis lexingtonensis** Labeda, Donahue, Williams, Sells and Henton 2003, 1603[VP]

lex.ing.ton.en′sis. N.L. fem. adj. *lexingtonensis* from Lexington, named after the place of origin, Lexington, Kentucky, USA.

Forms an abundant dark orange-brown to dark reddish-brown substrate mycelium, a light yellow to purplish-tan aerial mycelium, and a dark red to reddish-brown soluble pigment on most media. Grows between 15 to 42°C.

Hippurate is hydrolyzed, but does not degrade adenine. Acid is produced from dulcitol (weak), but not from methyl α-D-glucoside. Acetate, citrate, oxalate, and propionate are used as sole carbon sources, but not benzoate, lactate, malate, mucate, succinate, or DL-tartrate. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{15:0}$ iso (10.2%) and $C_{16:0}$ iso (42.9%), and smaller proportions (<10%) of $C_{14:0}$ iso (4.1%), $C_{15:0}$ anteiso (1.2%), $C_{15:1}$ (1.7%), $C_{15:0}$ (4.2%), $C_{16:1}$ *cis*9 (4.0%), $C_{16:0}$ (2.2%), 9-methyl-$C_{16:0}$ (1.5%), $C_{17:0}$ iso (2.1%), $C_{17:0}$ anteiso (1.7%), $C_{17:1}$ *cis*9 (7.8%), $C_{16:0}$ 2-OH (7.8%), $C_{17:0}$ (3.3%), and $C_{17:0}$ 10-methyl (1.8%). The major phospholipid is PE. The predominant menaquinone is MK-9(H_4).

Source: isolated from an equine placenta.

DNA G+C content (mol%): not determined.

Type strain: LDDC 12275-99, DSM 44653, JCM 12672, NRRL B-24131.

Sequence accession no. (16S rRNA gene): AY183358.

18. **Amycolatopsis lurida** (Lechevalier, Prauser, Labeda and Ruan 1986) Stackebrandt, Kroppenstedt, Wink and Schumann 2004, 267[VP] [Basonym: *Amycolatopsis orientalis* subsp. *lurida* (*ex* Grundy, Sinclair, Theriault, Goldstein, Rickher, Warren, Oliver and Sylvester 1957) Lechevalier, Prauser, Labeda and Ruan 1986, 35; "*Nocardia lurida*" Grundy, Sinclair, Theriault, Goldstein, Rickher, Warren, Oliver and Sylvester 1957, 687.]

lu′ri.da. L. fem. adj. *lurida* pale yellow, sallow.

White aerial mycelium carries cylindrical, occasionally ovoid, smooth spores in straight to flexuous chains. Yellow to beige substrate mycelium branches frequently and appears to be slightly zig-zag. Grows at 10°C, but not at 45°C.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, esterase lipase, (C8), β-galactosidase, β-glucosidase, leucine arylamidase, lipase (C14), naphthol-AS-BI-phosphohydrolase, and trypsin, but negative for esterase (C4), cystine arylamidase, α-fucosidase, α-galactosidase, α-glucosidase, β-glucuronidase, α-mannosidase, and valine arylamidase (API ZYM tests). Positive for β-galactosidase, but not for arginine dihydrolase, or lysine and ornithine decarboxylases (API 20E tests). Acetoin positive, but indole-negative. Arbutin is hydrolyzed, but does not produce H_2S. Elastin and xylan are degraded, but not Tween 40 or uric acid.

Resistant (filter paper discs soaked in µg/ml) to nalidixic acid (30), streptomycin (10) and vancomycin (30), but sensitive to kanamycin (30) and sulfonamide (200). Grows in the presence of lysozyme. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Mycolic acids are present. The polar lipid pattern contains DPG as the diagnostic component. The predominant menaquinones are MK-9(H_2,H_4).

Source: isolated from soil.

DNA G+C content (mol%): 67 (T_m).

Type strain: ATCC 14930, DSM 43134, IFO (now NRBC) 14500, JCM 3141, LMG 4064, NRRL 2430, NRRL WC-3860, VKM Ac-1242.

Sequence accession nos: AJ577997 (16S rRNA gene); EU822900 (*gyrB*).

19. **Amycolatopsis marina** Bian, Li, Wang, Song, Liu, Dai, Ren, Gao, Hu, Liu, Li and Zhang 2009, 480[VP]

ma.ri′na. L. fem. adj. *marina* of the sea, marine.

Sparse, white aerial mycelium and branched yellow to yellow-brown substrate mycelium fragment into rod-like elements on yeast extract-malt extract agar medium (ISP medium 2). Diffusible pigments are not produced. Grows between 10 and 45°C (optimally at 28°C) and at pH 6–9 (optimally between pH 7 and 8).

H_2S is not produced. Tweens 20, 40, 60, and 80 are degraded, but not adenine or elastin. Cellobiose, fructose, galactose, maltose, mannitol, *myo*-inositol, rhamnose, ribose, trehalose, xylitol, and sodium acetate are used as sole carbon sources, but not DL-arabinose, methyl-D-lactose, raffinose, sorbitol, sucrose, or sodium citrate dehydrate (all at 1%, w/v). Grows in the presence of 12% (w/v) NaCl.

Resistant (filter paper discs soaked in 30 µg/ml antibiotic) to amikacin, carbenicillin, clarithromycin, kanamycin, penicillin G, rifampin, sulfamethoxazole and tobramycin, but sensitive to acetylspiramycin, carbenicillin, cephalothin, chloramphenicol, doxycycline, erythromycin, gentamicin, midecamycin, minocycline, novobiocin, and streptomycin. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{16:0}$ iso (40.4%) and $C_{16:0}$ iso 2-OH (11.4%), and smaller proportions (<10%) of $C_{17:1}$ *cis*9 (8.6%), $C_{16:1}$ *cis*9, (7.8%), $C_{16:0}$ (7.1%), $C_{17:0}$, (4.9%), $C_{17:0}$ iso (3.5%), $C_{15:0}$ (2.9%), $C_{16:1}$ iso H (2.7%), $C_{17:0}$ anteiso (2.3%), $C_{15:1}$ B (1.6%), $C_{15:0}$ iso (1.5%), $C_{16:0}$ 10-methyl (1.4%), $C_{18:0}$ (1.4%), $C_{18:1}$ *cis*9 (1%), $C_{14:0}$ iso (0.9%), and $C_{18:0}$ iso (0.8%). The polar lipid pattern contains DPG, PE, PG, PI, PIMs, and PME. The predominant menaquinone is MK-9(H_4) (79%); also contains minor amounts of MK-8(H_4).

Source: isolated from a sediment sample collected from the South China Sea.

DNA G+C content (mol%): 70.1 (HPLC).

Type strain: Ms392A, CGMCC 4.3568, NBRC 104263.

Sequence accession no. (16S rRNA gene): EU329845.

20. **Amycolatopsis mediterranei** (Margalith and Beretta 1960) Lechevalier, Prauser, Labeda and Ruan 1986, 35[VP] [Basonym: *Nocardia mediterranei* (Margalith and Beretta 1960) Thiemann, Zucco, Pelizza 1969, 106; "*Streptomyces mediterranei*" Margalith and Beretta 1960, 321.]

med.i.ter.ra′ne.i. L. neut. gen. n. *mediterranei* of the interior of the land, from the Mediterranean area.

Substrate hyphae may show a zig-zag appearance. Aerial hyphae, when formed, differentiate into long, straight to flexuous chains of ellipsoid to oblong spores. Yellow colored colonies are formed on modified Bennett's agar. Grows from 10 to 42°C, but not at 45°C.

Acid and alkaline phosphatase-positive, but is negative for *N*-acetyl-β-glucosamidase, α-chymotrypsin, cystine arylamidase, esterase (C4), esterase lipase C8), α-fucosidase, α- and β-galactosidases, α- and β-glucosidases, leucine arylamidase, lipase (C14), α-mannosidase, naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase. Acetate, citrate, lactate, malate, oxalate, propionate, pyruvate, and succinate are decarboxylated, but not benzoate, mucate, or tartrate.

Resistant (µg/ml) to gentamicin sulfate (5), neomycin sulfate (8), tobramycin sulfate (8), novobiocin (10), polymyxin B (50), rifampin (10) and vancomycin hydrochloride (0.25). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Muramic acid moieties are *N*-acetylated. The cellular fatty acid profile contains major proportions of $C_{16:0}$ iso (44.9%), and smaller proportions (<10%) of $C_{14:0}$ iso (1.2%), $C_{15:0}$ iso (9.3%), $C_{15:0}$ anteiso (1.4%), $C_{15:1}$ (2.0%), $C_{15:0}$ (3.1%), $C_{16:1}$ iso H (2.3%), $C_{16:0}$ (1.0%), $C_{16:1}$ *cis*9 (1.3%), $C_{17:1}$ iso G (1.5%), $C_{17:0}$ iso (2.0%), $C_{17:0}$ anteiso (4.0%), $C_{17:1}$B (6.1%), $C_{17:1}$ C (9.0%), $C_{17:0}$ C (2.9%), and $C_{18:1}$ (5.6%). Does not contain mycolic acids. The predominant menaquinones are MK-9(H_4) and MK-9(H_6).

Source: isolated from a soil sample collected in a *Pinus* arboretum near St Raphael in France.

DNA G+C content (mol%): 67–69 (T_m).

Type strain: ATCC 13685, CCUG 43144, CIP 107074, DSM 43304, NBRC 13415, IMET 7651, ISP 5501, JCM 4789, KCTC 1739, NRRL B-3240, VKM Ac-798.

Sequence accession nos: AJ293754 (16S rRNA gene); EU822901 (*gyrB*).

Additional comments: Amycolatopsis mediterranei DSM 46095 and DSM 40696 have been reclassified as *Amycolatopsis rifamycinica* (Bala et al., 2004).

21. **Amycolatopsis methanolica** de Boer, Dijkhuizen, Grobben, Goodfellow, Stackebrandt, Parlett, Whitehead and Witt 1990, 203[VP]

me.tha.no′li.ca. N.L. n. *methanol* methanol; L. fem. suff. -*ica* suffix used with the sense of pertaining to; N.L. fem. adj. *methanolica* relating to methanol.

Forms a yellow substrate mycelium which bears white aerial hyphae that differentiate into smooth, squarish to oval spores (0.4 × 0.6–0.8 µm) on long, straight to flexuous chains on Czapek Dox agar. Grows from 10 to 50°C.

Decomposes DNA and elastin, but not adenine, arbutin, or tributyrin. Acetate, benzoate, fumarate, 2-oxoglutarate, lactate, malate, propionate, pyruvate, and succinate are used as sole carbon sources, but not citrate, formate, oxalate or gluconate. Acid is produced from ribose, but not from dulcitol.

Resistant to (µg/ml) cephaloridine hydrochloride (10), gentamicin sulfate (5), lincomycin hydrochloride (10), neomycin sulfate (10), oleandomycin phosphate (2), penicillin G (20), novobiocin (10), polymyxin B (50), and vancomycin hydrochloride (0.25), but sensitive to lysozyme. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The cellular fatty acid profile contains major proportions of $C_{16:0}$ iso (32.0%), $C_{16:0}$ (24.3%), and $C_{17:0}$ anteiso (21.8%). Mycolic acids are absent. The polar lipid pattern contains DPG, PE, PME, and PIMs. The predominant menaquinones are MK-9(H_2,H_4).

Source: isolated from a soil sample collected in New Guinea.

DNA G+C content (mol%): not determined.

Type strain: 239, DSM 44096, NBRC 15065, IMSNU 20055, JCM 8087, LMD 80.32, NCIB (now NCIMB) 11946, NRRL B-24139.

Sequence accession nos: AJ249135 (16S rRNA gene); EU822902 (*gyrB*).

Additional comments: the type strain of *Amycolatopsis methanolica* cleaves a broad range of 7-amino-methylcoumarin and 4-methylumbelliferone conjugated substrates and grows in a mineral medium broth containing diverse sole carbon compounds (De Boer et al., 1990).

22. **Amycolatopsis minnesotensis** Lee, Kinkel and Samac 2006c, 268[VP]

min.ne.sot.en′sis. N.L. fem. adj. *minnesotensis* pertaining to Minnesota, the origin of the soil sample from which the type strain was isolated.

Forms a well-developed, white aerial mycelium and a yellow vegetative mycelium that fragment into rod-shaped elements. Grows from 10 and 30°C, but not at 37°C.

Positive for acid and alkaline phosphatase, esterase (C4), and naphthol-AS-BI-phosphohydrolase, but negative for α-chymotrypsin, cystine arylamidase, α- and β-galactosidases, α-glucosidase, lipase (C14), α-mannosidase, trypsin, and valine arylamidase. Acid is produced from D-xylitol, but not from 2,3-butanediol, dextran, dulcitol, or 1,2-propanediol. Additional phenotypic properties are shown in Table 238.

Resistant (filter paper discs soaked in µg/ml) to kanamycin (30), streptomycin (10) and vancomycin (30), but sensitive to nalidixic acid (30) and sulfonamide (200).

Predominant menaquinones are MK-9(H_4); major fatty acids are $C_{16:0}$ iso, $C_{16:0}$, $C_{15:0}$ iso, and $C_{17:0}$.

Source: isolated from a prairie soil.

DNA G+C content (mol%): 69.5.

Type strain: 32U-2, DSM 44988, JCM 14545, KCCM 42246, NRRL B-24435.

Sequence accession nos: DQ076482 (16S rRNA gene); EU822903 (*gyrB*).

23. **Amycolatopsis nigrescens** Groth, Tan, González, Laiz, Carlsohn, Schütze, Wink and Goodfellow 2007, 517[VP]

ni.gres′cens. L. part. adj. *nigrescens* becoming black.

Forms extensively branched hyphae (0.7–0.9 µm in diameter) that fragment into squarish rod-like elements. The color of the substrate mycelium changes from orange to black with the production of a dark reddish-black soluble pigment. The substrate mycelium carries sparse to moderate white or pale-orange aerial hyphae. Grows between 20 and 40°C, but not at 10 or 42°C, and between pH 5 and 9 but not at pH 4.5 or 10.

Tween 80 is degraded, but not adenine. Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, cystine arylamidase, esterase (C4), esterase lipase (C8), leucine arylamidase, lipase (C14), naphthol-AS-BI-phosphohydrolase, and valine arylamidase, but negative for α-galactosidase, α-glucosidase, α-mannosidase, and trypsin (API ZYM tests).

Hippurate is hydrolyzed. L-arabinose, fructose, glucose, mannitol, *myo*-inositol, raffinose, and xylose are used as sole carbon sources, but not cellulose, or sucrose. Similarly, acetate, aconitate, citrate, malate, and succinate are used as sole carbon sources, but not benzoate or DL-tartrate. Grows in the presence of 6% (w/v) NaCl.

Resistant (filter paper discs soaked in µg/ml) to lincomycin hydrochloride (2), kanamycin (30), meticillin (5), nalidixic acid (30), norfloxacin (10), streptomycin (10), sulfonamide (200), and vancomycin (30), but sensitive to chloramphenicol (30), imipenem (10), ofloxacin (10), oxytetracycline hydrochloride (30), and rifampin (30). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Muramic acid moieties are *N*-acetylated. The cellular fatty acid profile contains major proportions of $C_{16:0}$ iso (27–28%), and smaller proportions (<10%) of $C_{17:0}$ (7.3–9.3%), $C_{17:1}$ *cis*9 (8.4–9.8%), $C_{16:0}$ (7.2–7.4%), $C_{16:0}$ iso 2-OH (6.4–7.9%), $C_{15:0}$ iso (5.2–5.7%), $C_{18:1}$ *cis*9 (4.8–4.9%), $C_{16:1}$ iso (4.2–4.4%), $C_{17:0}$ anteiso (3.7–3.8%), $C_{16:1}$ *cis*9 (3.1–3.8%), $C_{18:0}$ (3.3%), and an unidentified component (3.0–3.7%). Mycolic acids are absent. The polar lipid pattern includes DPG, HPE, PG, PI, and PS. The predominant menaquinone is MK-11(H_4) (52–54%); also contains smaller proportions of MK-12(H_4) (18%), MK-9(H_4) (8–9%), and MK-10(H_4) (9%).

Source: isolated from the wall of St Callistus hypogean Roman catacomb.

DNA G+C content (mol%): not determined.

Type strain: CSC17Ta-84, DSM 44992, HKI 0330, JCM 14717, NRRL B-24473.

Sequence accession nos: DQ486888 (16S rRNA gene); EU822904 (*gyrB*).

24. **Amycolatopsis niigatensis** Ding, Hirose and Yokota 2007, 1750[VP]

ni.i.ga.ten′sis. N.L. fem. adj. *niigatensis* referring to Niigata Prefecture, Japan, the source of the type strain.

The substrate mycelium is purple brown and the aerial mycelium white to light yellow. Grows between 5 to 45°C, optimally at 30°C, and from pH 6 to 11, optimally at pH 9.

Positive for *N*-acetyl-β-glucosamidase, alkaline phosphatase, α-chymotrypsin, cystine arylamidase, esterase (4), esterase lipase (C8), α- and β-galactosidases, α-glucosidase, leucine arylamidase, α-mannosidase, naphthol-AS-BI-phosphohydrolase, and valine arylamidase, but negative for α-fucosidase, β-glucosidase, and lipase (C14). Grows in the presence of 7% (w/v) NaCl. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acids contain a major proportion of $C_{16:0}$ iso (40%), and smaller proportions (<10%) of $C_{14:0}$ iso (7.1%), $C_{14:0}$ (0.4%), $C_{15:0}$ iso (9.3%), $C_{15:0}$ anteiso (7.7%), $C_{15:0}$ (4.5%), $C_{16:0}$ (2.1%), $C_{16:1}$ iso OH (2.6%), $C_{17:0}$ iso (1.6%), $C_{17:0}$ anteiso (6.9%), $C_{17:0}$ (2.6%), $C_{17:1}$ ω6*c* (6.6%), and $C_{17:1}$ ω8*c* (1.7%). Mycolic acids are absent. The predominant menaquinone is MK-9(H_4).

Source: isolated from filtration material made from volcanic soil, Niigata, Japan.

DNA G+C content (mol%): 72.4 (HPLC).

Type strain: LC11, CCTCC AB206020, IAM 15388, JCM 21832.

Sequence accession nos: AB248537 (16S rRNA gene); EU822905 (*gyrB*).

25. **Amycolatopsis palatopharyngis** Huang, Paściak, Liu, Xie and Gamian 2004, 361[VP]

pa.la.to.pha.ryn′gis. N.L. n. *palatopharynx* palatopharynx; N.L. gen. n. *palatopharyngis* of the palatopharynx.

Forms a branched yellow to yellow-brown substrate mycelium that fragments into rod-like elements. White aerial hyphae are produced sparsely on Bennett's, glucose-yeast extract-malt extract, and brain-heart infusion agars and moderately on inorganic salts-starch agars. Aerial hyphae differentiate into long chains of spore-like structures. Diffusible pigments are not produced. Grows between 10 and 40°C, but not at 45°C, and between pH 6 and 10. Grows in the presence of 10% (w/v) NaCl.

Resistant (µg/ml) to ampicillin (10), carbenicillin (100), and cephalothin (30), but sensitive to acetylspiramycin (15), chloramphenicol (30), clarithromycin (10), doxycycline (30), gentamicin (10), kanamycin (30), midecamycin (15),

minocycline (30), novobiocin (5), penicillin (30), rifampin (5), streptomycin (10), and tobramycin (10). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The cellular fatty acid profile contains major proportions (<10%) of $C_{16:0}$ iso (50.3%), $C_{16:0}$ (21.7%), and $C_{17:0}$ anteiso (12.4%), and smaller proportions of $C_{16:0}$ anteiso (3.6%), $C_{17:0}$ (8.5%), and $C_{18:0}$ (3.7%). Mycolic acids are absent. The polar lipid pattern includes PE, DPG, and PI. The predominant menaquinone is MK-9(H_4).

Source: isolated from an infected palatopharyngeal mucosa of an elderly human patient.

DNA G+C content (mol%): 65.8 (T_m).

Type strain: 1BDZ, AS 4.1729, DSM 44832, JCM 12460, PCM 2600.

Sequence accession nos: AF479268 (16S rRNA gene); EU822907 (*gyrB*).

26. **Amycolatopsis plumensis** Saintpierre-Bonaccio, Amir, Pineau, Tan and Goodfellow 2005, 2060[VP]

plum.en′sis. N.L. fem. adj. *plumensis* referring to the Plum region of the main island of New Caledonia, the source of the soil from which the type strain was isolated.

Forms extensively branched substrate hyphae that fragment into squarish, rod-like elements. A pale-orange substrate mycelium is formed on modified Bennett's agar, but diffusible pigments are absent. The substrate mycelium carries abundant pale-orange aerial hyphae. Grows between 20 and 37°C, but not at 10 or 45°C, and between pH 4 to12.

H_2S is formed. Elastin, Tween 80, and xylan are degraded.

Resistant (μg/ml) to erythromycin (4), gentamicin sulfate (10), rifampin (6), and streptomycin sulfate (5). Grows in the presence of crystal violet (0.0002%, w/v), phenol (0.01%, w/v), and potassium tellurite (0.005%, w/v). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The predominant menaquinone is MK-9(H_4).

Source: isolated from brown hypermagnesian ultramafic soil at the southern end of the main island of New Caledonia.

DNA G+C content (mol%): not determined.

Type strain: SBHS Strp1, DSM 44776, JCM 13852, NBRC 102106, NRRL B-24324.

Sequence accession nos: AY262825 (16S rRNA gene); EU822908 (*gyrB*).

27. **Amycolatopsis pretoriensis** Labeda, Donahue, Williams, Sells and Henton 2003, 1604[VP]

pre.tor.i.en′sis. N.L. fem. adj. *pretoriensis* from Pretoria, named after the place of origin, Pretoria, South Africa.

Forms a well-developed grayish-yellow to orange-brown substrate mycelium and an abundant white to orange-white aerial mycelium on most media. Faint soluble pigments are produced on some media, such as yeast extract-malt extract agar. Grows from 15 to 37°C.

Positive for cystine arylamidase and β-galactosidase, but negative for α-fucosidase, β-glucosidase, and valine arylamidase (API ZYM tests). Hippurate is hydrolyzed. Acid is produced from dulcitol, but not from methyl β-xyloside or melezitose. Acetate, benzoate (weak), citrate (weak), and lactate (weak) are used as a sole carbon sources, but not malate, mucate, or tartrate. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acid profiles contain major proportions of $C_{16:0}$ iso (45.5%) and $C_{16:0}$ 2-OH (12.3%), and smaller proportions (<10%) of $C_{14:0}$ iso (3.4%), $C_{15:0}$ iso (7.9%), $C_{15:1}$ (3.3%), $C_{15:0}$ (3.1%), $C_{17:0}$ anteiso (1.3%), $C_{17:1}$ *cis*9 (8.9%), $C_{17:0}$ (2.7%), and $C_{17:0}$ 10-methyl (2.6%). The major polar lipids are PE and PME. The predominant menaquinones are MK-9(H_2) and MK-9(H_4).

Source: isolated from an equine placenta in Pretoria, South Africa.

DNA G+C content (mol%): not determined.

Type strain: ARC OVI 0181, DSM 44654, JCM 12673, NRRL B-24133.

Sequence accession no. (16S rRNA gene): AY183356.

28. **Amycolatopsis regifaucium** Tan, Robinson, Lacey, Brown, Kim and Goodfellow 2007, 2566[VP]

re.gi.fau′ci.um. L. n. *rex regis* king; L. gen. pl. n. *faucium* of a defile; N.L. gen. pl. n. *regifaucium* of King's Canyon, Australia, the source of the soil from which the first strains were isolated.

Forms an extensively branched substrate mycelium which fragments into squarish, rod-like elements. An abundant, light-gray aerial mycelium and a dark yellow–brown substrate mycelium with filamentous edges are formed on modified Bennett's agar supplemented with mannitol and soybean flour; a dark gray–brown diffusible pigment is also produced. Grows between 10 and 37°C, and between pH 5 and 10.

Arbutin is hydrolyzed. Elastin, Tween 40, uric acid, and xylan are degraded. L-Arabinose, arabitol, cellobiose, dextrin, galactose, glucose, glycerol, glycogen, *myo*-inositol, maltose, mannitol, methyl α-D-glucoside, ribose, sucrose, glycogen, and xylitol are used as sole carbon sources, but not adonitol, *meso*-erythritol, melezitose, melibiose, raffinose, or sorbitol.

Resistant (μg/ml) to gentamicin sulfate (5), neomycin sulfate (8), novobiocin (10), penicillin G (20), polymyxin B sulfate (50), rifampin (10), streptomycin sulfate (16), and tobramycin sulfate (8). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Does not contain mycolic acids. The polar lipid pattern includes DPG, PE, PG, PI, PIMs, and PME. The predominant menaquinone is MK-9(H_4) (71%); also contains MK-9(H_6) (29%).

Source: isolated from an arid soil collected from King's Canyon, Australia.

DNA G+C content (mol%): not determined.

Type strain: GY080, DSM 45072, JCM 15588, NCIMB 14277.

Sequence accession nos: AY129760 (16S rRNA gene); EU822909 (*gyrB*).

29. **Amycolatopsis rifamycinica** Bala, Khanna, Dadhwal, Prabagaran, Shivaji, Cullum and Lal 2004, 1148[VP]

rif.a.my.ci′na. N.L. n. *rifamycinum* rifamycin; L. suff. *-icus -a -um* related to; N.L. fem. adj. *rifamycinica* referring to the ability to produce rifamycin.

Orange-colored substrate mycelium is produced on yeast extract and glucose-asparagine agars and a white to very pale pink aerial mycelium is produced on oatmeal and yeast extract-molasses agars. A light pale to brown yellow pigment is formed on tyrosine, yeast extract-glucose, and oatmeal agars. Grows from 10 to 37°C, but not at 45°C.

Positive for cystine arylamidase, β-galactosidase, β-glucosidase, and valine arylamidase, but negative for α-fucosidase (API ZYM tests). Additional phenotypic properties are shown in Table 238.

The cellular fatty acid profile contains major proportions of $C_{16:0}$ iso (24%), $C_{17:0}$ anteiso (11%), and $C_{18:1}$ (25%), and smaller proportions (<10%) of $C_{15:0}$ iso (3%), $C_{16:0}$ (4%), iso $C_{17:0}$ (9%), $C_{17:1}$ (4%), and $C_{18:4}$ (4%). The polar lipid pattern includes cardiolipin, PE, PG, and PI.

Source: isolated from a soil sample in an arid region near Alice Springs, Northern Territory, Australia.

DNA G+C content (mol%): not determined.

Type strain: nt 19, ATCC 27643, DSM 46095, JCM 12674.

Sequence accession nos: AY083603 (16S rRNA gene); EU822910 (*gyrB*).

Additional comments: DNA restriction profiles of seven *Amycolatopsis mediterranei* strains provided further evidence that strain DSM 46095 was misclassified in this species (Bala et al., 2004), a result in line with the results of an earlier study (Kaur et al., 2001).

30. **Amycolatopsis rubida** Huang, Qi, Lu, Liu and Goodfellow 2001, 1096[VP]

ru.bi′da. L. fem. adj. *rubida* reddish.

Forms branching white to yellowish substrate mycelium which fragments into squarish elements (0.4–0.5 × 1.2–3.0 µm). An abundant white aerial mycelium which fragments into squarish elements is produced on modified Bennett's agar. A reddish diffusible pigment is formed on glucose-asparagine agar. Grows between 10 and 40°C. Grows in the presence of 7% (w/v) NaCl.

Resistant (µg/ml) to gentamicin sulfate (5), neomycin sulfate (8), novobiocin (10), penicillin G (20), polymyxin B (50), streptomycin sulfate (30), tobramycin sulfate (8), and vancomycin hydrochloride (0.25), but sensitive to chloramphenicol (30) and erythromycin (15). Also resistant to lysozyme (0.005%, w/v). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The cellular fatty acid profile contains major proportions of $C_{14:0}$ iso (11.3%), $C_{15:0}$ (14.6%), $C_{15:1}$ ω6*c* (12.8%), $C_{16:0}$ iso (12.8%) and $C_{17:0}$ (11.3%), and smaller proportions (<10%) of $C_{14:0}$ (0.5%), $C_{15:0}$ iso (6.8%), $C_{15:0}$ anteiso (3%), $C_{16:0}$ (5.2%), $C_{16:1}$ iso H (0.2%), $C_{17:0}$ iso (0.4%), $C_{17:0}$ anteiso (0.8%), and $C_{18:0}$ (0.4%). Mycolic acids are absent. The polar lipid pattern includes DPG, PE, PIMs, and PME. The predominant menaquinone is MK-9(H_4).

Source: isolated from coniferous forest soil collected in Guangxi Province, China.

DNA G+C content (mol%): 67.4 (T_m).

Type strain: 13.4, AS4. 1541, CIP 107102, DSM 44637, JCM 10871 NBRC 100041, NRRL B-24150.

Sequence accession nos: AF222022 (16S rRNA gene); EU822911 (*gyrB*).

31. **Amycolatopsis saalfeldensis** Carlsohn, Groth, Tan, Schütze, Saluz, Munder, Yang, Wink and Goodfellow 2007, 1644[VP]

sa.al.fel.den′sis. N.L. fem. adj. *saalfeldensis* from Saalfeld, named after the place of origin, a town in Thuringia, Germany.

Forms extensively branched substrate mycelium (hyphal diameter 0.5–0.6 µm) that fragments into squarish rod-like elements on oatmeal and yeast-extract-malt extract agars. The substrate mycelium carries moderate amounts of white aerial hyphae on oatmeal agar which fragment into squarish rod-like elements. Diffusible pigments are not produced. Grows between 20 and 35°C, and between pH 4.5 and 8, but not at pH 9.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, α-chymotrypsin, esterase (C4), esterase lipase (C8), α-glucosidase, naphthol-AS-BI-phosphohydrolase, and valine arylamidase, but negative for cystine arylamidase, α-fucosidase, α- and β-galactosidases, lipase (C14), α-mannosidase, and trypsin (API ZYM tests). Hippurate is hydrolyzed, and H_2S and oxidase are produced, but does not form indole. Tween 80 is degraded, but not adenine. L-Arabinose, fructose, glucose, *myo*-inositol, mannitol, raffinose, rhamnose (weakly), sucrose, and xylose are used as sole carbon sources, but not cellulose (all at 1%, w/v). Similarly, acetate, aconitate, benzoate (weakly), citrate, malate, and succinate are used as sole carbon sources, but not DL-tartrate (all at 0.2%, w/v).

Resistant (filter paper discs soak in µg/ml) to ampicillin (10), methicillin (5), norfloxacin (10), novobiocin (5), penicillin G (10 IU), and polymyxin B (300 IU), but sensitive to chloramphenicol (30), ciprofloxacin (5), imipenem (10), kanamycin sulfate (30), lincomycin hydrochloride (2), ofloxacin (10), oxytetracycline hydrochloride (30), rifampin (30), streptomycin sulfate (10), and vancomycin hydrochloride (30). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Muramic acid moieties are *N*-acetylated. Cellular fatty acid profiles contain major proportions of $C_{16:0}$ iso (41–42%), and smaller proportions of $C_{17:0}$ iso (8–10%), $C_{14:0}$ iso (7–9%), $C_{15:0}$ iso (8–9%), $C_{16:0}$ iso 2-OH (4–6%), $C_{15:0}$ (6%), $C_{17:0}$ (5–7%), and $C_{17:0}$ iso (8–10%). Mycolic acids are absent. The polar lipid pattern includes DPG, hydroxyphosphatidylethanolamine, PE, PG, and PS. The predominant menaquinone is MK-9(H_4) (86.9%); also contains minor amounts of MK-8(H_4) (4.5%), MK-9(H_6) (1.0–3.0%), and MK-10(H_4) (2.0%).

Source: isolated from the surface of rocks in a medieval alum slate mine.

DNA G+C content (mol%): not determined.

Type strain: HKI 0457, DSM 44993, JCM 14909, NRRL B-24474.

Sequence accession nos: DQ792500 (16S rRNA gene); EU822912 (*gyrB*).

Additional comments: grows on minimal medium supplemented with $CuSO_4$ (2 mM) and $NiCl_2$ (5 mM) (Carlsohn et al., 2007). The type strain DSM 44993 was mistakenly cited as DSM 44493 in the protologue of the valid publication.

32. **Amycolatopsis sacchari** Goodfellow, Kim, Minnikin, Whitehead, Zhou and Mattinson-Rose 2001, 191[VP]

sac′char.i. N.L. n. *Saccharum* generic name of sugar cane; N.L. gen. n. *sacchari* of sugar cane.

Forms branched substrate mycelium that fragments into rod-like elements when grown on modified Bennett's and Czapek Dox-yeast extract-casein (CYC) agars. The substrate mycelium carries moderate to abundant white aerial hyphae which differentiate into straight chains of spore-like structures on CYC agar. Diffusible pigments are not produced. Grows between 20 and 45°C, but not at 55°C, and between pH 5 and 8.

Positive for alkaline phosphatase, α-chymotrypsin, cystine arylamidase, esterase (C4), α-glucosidase, lysine (C14), naphthol-AS-BI-phosphohydrolase, and valine arylamidase, but negative for α- and β-galactosidases, α-mannosidase, and trypsin. Testosterone, and Tweens 20, 40, 60 and 80 are degraded. Adonitol, D- and L-arabinose, cellobiose, dextrin, *meso*-erythritol, fructose, D- and L-fucose, galactose, gentiobiose, glycerol, glycogen, lactose, maltose, mannitol, mannose, methyl α-D-glucoside, methyl β-D-glucoside, rhamnose, ribose, salicin, sorbose, sucrose, trehalose, xylitol, and xylose are used as sole carbon sources, but not amygdalin, arabitol, dulcitol, *myo*-inositol, melibiose, sorbitol, or tyrosine (all at 1%, w/v). Similarly, L-alanine, androsterone, arbutin, butan-1-ol, butyrate, ergosterol, ethanol, hippurate, propan-1-ol, propan-2-ol, propionate, propylase glycol, protocatechuic acid, pyruvate, quinic acid, L-serine, shikimic acid, succinate, testosterone, and tyrosine are used as sole carbon sources, but not acetamide, benzamide, catechol, L-citrulline, *p*-cresol, fumarate, *m*- or *p*- hydroxybenzoic acid, β-hydroxybutyric acid, 15-mandelic acid, squalene, syringealdehyde, tartrate, trimethylamine, or vanillin (at 0.1% w/v or v/v).

Grows in the presence of (μg/ml) bismuth citrate (10), crystal violet (1), phenol (100), phenyl ethanol (4000), potassium tellurite (10), sodium azide (10), sodium chloride (7%, w/v), teepol (100), tetrazolium (100), and thallous acetate (10), but sensitive to bismuth citrate (100), crystal violet (100), sodium chloride (10), tetrazolium (1000), and thallous acetate (100).

Resistant to (μg/ml) cephaloridine hydrochloride (250), chloramphenicol (50), demeclocycline hydrochloride(8), gentamicin sulfate (5), kanamycin sulfate (5), lincomycin hydrochloride (10), neomycin sulfate (10), nalidixic acid (30), oleandomycin phosphate (2), penicillin G (20), polymyxin B sulfate (50), rifampin (2), streptomycin sulfate (16), tobramycin sulfate (8), and vancomycin hydrochloride (0.25), but sensitive to kanamycin sulfate (50) and tetracycline hydrochloride (5). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The cellular fatty acid profile contains major proportions of $C_{17:0}$ anteiso (30–58%), and smaller proportions of $C_{16:0}$ (4–14%), $C_{17:0}$ (2–5%), $C_{17:1}$ (1–3%), $C_{17:0}$ anteiso (7–11%), and $C_{17:0}$ iso (7–11%). Mycolic acids are absent. The polar lipid pattern includes DPG, PE, PG, and PI. The predominant menaquinone is MK-9(H_4) (96%).

Source: isolated from sugar cane bagasse and from floor dust of a hemp factory.

DNA G+C content (mol%): not determined.

Type strain: K24, CIP 107029, DSM 44468, JCM 11272, KCTC 9863, NBRC 100339.

Sequence accession nos: AF223354 (16S rRNA gene); EU822913 (*gyrB*).

Additional comments: cleaves a broad range of 7-amino-4-methyl coumarin and 4-methylumbelliferone conjugated substrates (Goodfellow et al., 2001).

33. **Amycolatopsis sulphurea** Lechevalier, Prauser, Labeda and Ruan 1986, 35[VP] ("*Nocardia sulphurea*" Oliver and Sinclair 1964)

sul.phu′re.a. L. n. *sulphur* sulfur; L. masc. suff. *-eus* suffix used with various meanings; N.L. fem. adj. *sulphurea* of sulfur, referring to the yellow color of the substrate hyphae.

Forms a white to yellowish to olive substrate mycelium, which tends to break down into fragments. The aerial mycelium is light yellow. A dark brown diffusible pigment is produced on modified Bennett's agar. Grows between 10 to 37°C.

Does not degrade adenine. Acetate, citrate, lactate, malate, propionate, pyruvate, and succinate are used as sole carbon sources, but not benzoate, mucate, oxalate, or tartrate.

Resistant (μg/ml) to lysozyme, neomycin sulfate (4), tobramycin sulfate (8), novobiocin (10), polymyxin B (50), and vancomycin hydrochloride (0.25). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Mycolic acids are absent. The cellular fatty acid profile contains major proportions of $C_{16:0}$ iso (21.0%) and $C_{16:0}$ (17.0%), and smaller proportions (<10%) of $C_{14:0}$ iso (3–7%), $C_{15:0}$ iso (9–3%), $C_{15:0}$ anteiso 5.0%), $C_{15:0}$ (3–4%), *cis*9 $C_{16:0}$ (3–9%), $C_{17:0}$ iso (2.0%), $C_{17:0}$ anteiso (5–6%), $C_{17:1}$ (8–9%), $C_{17:0}$ iso (9.3%), and $C_{18:0}$ (3.2%). The polar lipid pattern includes PE and PME. The predominant menaquinones are MK-9(H_2,H_4).

Source: isolated from soil.

DNA G+C content (mol%): 67 (T_m).

Type strain: ATCC 27624, DSM 46092, NBRC 13270, IMET 7649, JCM 3142, VKM Ac-1244.

Sequence accession nos: AF051343 (16S rRNA gene); EU822914 (*gyrB*).

Additional comments: the name "*Nocardia sulphurea*" Oliver and Sinclair (1964) was described in a patent which means that the name has not been effectively published [Rule 25b (5) Bacteriological Code]. Consequently, this nomenclatural name cannot be revived (Rule 28a) and the citation of *Nocardia sulphurea* cannot refer to the original authors.

34. **Amycolatopsis taiwanensis** Tseng, Yang, Li and Jiang 2006, 1814[VP]

tai.wan.en′sis. N.L. fem. adj. *taiwanensis* of Taiwan, where the type strain was isolated.

The substrate mycelium is light yellow on Bennett's, peptone-yeast extract-iron, tyrosine and yeast extract-malt extract agars; yellowish-white on glucose-asparagine, inorganic salts-starch and oatmeal agars, and purple-yellow on tryptone-yeast extract agars. Short chains of oval spores are formed, albeit poorly, on glycerol-asparagine, inorganic

salts, starch, and tyrosine agars. Soluble pigments are not formed. Does not produce aerial hyphae. Grows at 20–40°C. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Muramic acid moieties are *N*-acetylated. The cellular fatty acid profile contains major proportions of $C_{16:0}$ iso (38.1%), and $C_{17:1}$ (25.4%), and smaller proportions (<10%) of $C_{17:0}$ anteiso (5.2%), $C_{16:0}$ (5.1%), and $C_{17:0}$ (4.0%). Mycolic acids are not present. The diagnostic polar lipid is PE. The predominant menaquinone is MK-9(H_4).

Source: isolated from soil collected from Yilan county, Taiwan.

DNA G+C content (mol%): 68.9 (HPLC).

Type strain: 0345M-7, BCRC 16802, JCM 14925, KCTC 19116, NBRC 102103.

Sequence accession nos: DQ160215 (16S rRNA gene); EU822915 (*gyrB*).

35. **Amycolatopsis thermoflava** Chun, Kim, Oh, Seong, Lee, Bae, Lee, Kang, Hah and Goodfellow 1999, 1372[VP]

ther.mo.fla′va. Gr. n. *thermê* heat; L. adj. *flavus* yellow; N.L. fem. adj. *thermoflava* thermophilic, yellow.

Forms an extensively branched substrate mycelium which fragments into squarish elements (0.6–0.7 × 6.5–14.0 µm). Aerial hyphae are sterile, sparse, and white; the substrate mycelium is brown and a brown diffusible pigment is produced on modified Bennett's agar. Grows at 28–55°C, but not at 10 or 60°C.

Resistant (µg/ml) to gentamicin sulfate (5), neomycin sulfate (8), novobiocin (10), rifampin (10), tobramycin sulfate (8), and vancomycin hydrochloride (0.25). Grows in the presence of lysozyme. Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The cellular fatty acid profile contains major proportions of $C_{16:0}$ iso (29%), $C_{16:0}$ iso-α OH (16%), and $C_{17:0}$ anteiso (14%). Mycolic acids are not present. The predominant menaquinone is MK-9(H_4).

Source: isolated from a soil sample collected from Hainan Island, China.

DNA G+C content (mol%): 75.0 (T_m).

Type strain: N1165, CIP 106795, DSM 44574, NBRC 14333, JCM 10669, NRRL B-24140.

Sequence accession nos: AF052390 (16S rRNA gene); EU822916 (*gyrB*).

36. **Amycolatopsis tolypomycina** Wink, Kroppenstedt, Ganguli, Nadkarni, Schumann, Seibert and Stackebrandt 2003a, 935[VP] (Effective publication: Wink, Kroppenstedt, Ganguli, Nadkarni, Schumann, Seibert and Stackebrandt 2003b, 44.)

to.ly.po.my′ci.na. N.L. n. *tolypomycinum* tolypomycin (an antibiotic produced by the organism); L. fem. suff. *-ina* suffix used with the sense of belonging to; N.L. fem. adj. *tolypomycina* pertaining to tolypomycin.

The substrate mycelium is pure yellow on yeast extract-malt extract agar, melon yellow on oatmeal agar, yellow orange on inorganic salts-starch and tyrosine agars, and colorless on glycerol-asparagine agar; soluble pigments are not formed on any of these media. White, fragmenting aerial hyphae are produced on glycerol-asparagine, oatmeal, and tyrosine agars. Fragmentation of the substrate mycelium is seen on glycerol-asparagine, oatmeal, and tyrosine agars.

Positive for *N*-acetyl-β-glucosamidase, acid and alkaline phosphatases, cystine arylamidase, esterase (C8), α- and β-galactosidases, α-glucosidase, β-glucuronidase, leucine arylamidase, lipase (C14), α-mannosidase, trypsin, and valine arylamidase, but negative for esterase (C4), α-fucosidase, and naphthol-AS-BI-phosphohydrolase (API ZYM tests). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. Cellular fatty acids contain major proportions of $C_{16:0}$ iso (14.5%), $C_{15:0}$ iso (10.3%), and $C_{17:0}$ anteiso (15.2%), and smaller proportions of $C_{14:0}$ (0.6%), $C_{15:0}$ (3.3%), $C_{16:0}$ (7.7%), $C_{17:0}$ (7.5%), $C_{15:1}$ (1.0%), $C_{16:1}$ (6.1%), $C_{17:1}$ (8.9%), $C_{18:1}$ *cis*9 (1.0%), $C_{14:0}$ iso (0.8%), $C_{15:0}$ anteiso (3.6%), $C_{16:1}$ (0.8%), $C_{17:0}$ iso (4.1%), $C_{15:1}$ anteiso (0.5%), $C_{16:0}$ 10-methyl iso (0.4%), $C_{16:0}$ 10-methyl (2.6%), $C_{17:0}$ 10-methyl (3.1%), 2-hydroxyl-$C_{15:0}$ anteiso (0.5%), 2-hydroxy-$C_{16:0}$ iso (3.1%), 2-hydroxyl-$C_{17:0}$ anteiso (0.5%), and 2-hydroxyl-$C_{17:0}$ anteiso (3.9%). Mycolic acids are absent. The polar lipid pattern includes DPG, HPE, PE, PG, and PI. The predominant menaquinone is MK-9(H_4).

Source: isolated from soil in Tokyo, Japan.

DNA G+C content (mol%): not determined.

Type strain: ATCC 21177, DSM 44544, NBRC 14664, NRRL B-24205.

Sequence accession nos: AJ293757 (16S rRNA gene); EU822917 (*gyrB*).

37. **Amycolatopsis tucumanensis** Albarracin, Alonso-Vega, Trujillo, Amoroso and Abate 2010, 400[VP]

tu.cu.ma.nen′sis. N.L. fem adj. *tucumanensis* of or pertaining to Tucumán, Argentina, the origin of the soil sample from which the type strain was isolated.

Forms an extensively branched honey-yellow substrate mycelium that fragments into squarish elements on glycerol-asparagine, inorganic salts-starch, peptone-yeast extract, tyrosine, and yeast extract-malt extract agars; diffusible pigments are not formed on these media. A white aerial mycelium is produced on glycerol-asparagine, tyrosine, and yeast extract-malt extract agars. Aerial hyphae differentiate into straight to flexuous chains of spore-like elements (0.3–0.8 × 1.5 µm). Grows between 15 and 55°C and from pH 5.0 to 10.

Produces β-galactosidase, *N*-acetyl-β-glucosamidase, and phosphatase. Raffinose is used as a sole source of carbon, but not cellobiose, rhamnose, or xylose.

Resistant to lysozyme (100 µg/ml) and high concentrations of copper (up to 3 mM). Additional phenotypic properties are shown in Table 238.

Whole-organism hydrolysates are rich in arabinose and galactose. The fatty acid profile contains major proportions of $C_{16:0}$ iso (23%), $C_{16:0}$ (12%), and $C_{17:0}$ anteiso (11%). Mycolic acids are absent. The polar lipid pattern includes DPG, PI, and HPE. The predominant menaquinone is MK-9(H_4); also contains minor amounts of MK-9(H_2), MK-9(H_6), and MK-10(H_2).

Source: isolated from a sediment sample polluted with copper in Tucumán, Argentina.

DNA G+C content (mol%): not determined.

Type strain: ABO, BCCM/LMG 24814, DSM 45259.
Sequence accession no. (16S rRNA gene): DQ886938.

38. **Amycolatopsis ultiminotia** Lee 2009, 1403[VP]

ul.ti.mi.no′ti.a. L. sup. adj. *ultimus* farthest, extreme; L. fem. adj. *notia* southern; N.L. fem. adj. *ultiminotia* farthest southern, implying that the type strain was isolated from the southernmost part of the Republic of Korea.

Forms a white aerial mycelium and a cream to yellow substrate mycelium which fragment into rod-shaped elements. Grows from 10–37°C, but not at 42°C, and from pH 5.1 and 12.1.

DNA and elastin are degraded, but not chitin or cellulose. Acid is produced from dextran and dulcitol, but not from D-arabinose, inulin, methyl α-D-mannoside, ribose, sorbose, or xylitol.

Whole-organism hydrolysates are rich in arabinose and galactose. The cellular fatty acid profile contains major proportions of $C_{17:0}$ (23.7%), $C_{15:0}$ (19.8%), $C_{15:0}$ iso (10.0%), and $C_{16:0}$ iso (13.2%), and smaller proportions of $C_{13:0}$ (0.8%), $C_{14:0}$ (0.8%), $C_{14:0}$ iso (7.9%), $C_{14.0}$ 2-OH (3.3%), $C_{15:1}$ (1.7%), $C_{15:0}$ anteiso (2.7%), $C_{15:0}$ iso 3-OH (2.1%), $C_{17:0}$ anteiso (2.0%), $C_{17:0}$ iso (0.7%), $C_{18:0}$ (4.1%), and $C_{18:1}$ 0.7%). Does not contain mycolic acids. The polar lipid pattern consists of PME and an unknown ninhydrin-positive phospholipid. The predominant menaquinone is MK-9(H_4).

Source: isolated from the rhizosphere of a cliff associated plant (*Peucedanmum japonicium* Thunb).
DNA G+C content (mol%): 67.5.
Type strain: DSM 45180, NRRL B-24662.
Sequence accession no. (16S rRNA gene): FM177516.

39. **Amycolatopsis vancoresmycina** Wink, Kroppenstedt, Ganguli, Nadkarni, Schumann, Seibert and Stackebrandt 2003a, 935[VP] (Effective publication: Wink, Kroppenstedt, Ganguli, Nadharni, Schumann, Seibert and Stackebrandt 2003b, 44.)

van.co.res.my′ci.na. N.L. n. *vancoresmycinum* an antibiotic, vancoresmycin, produced by the organism; L. fem. suff. *-ina* suffix used with the sense of belonging to: N.L. fem. adj. *vancoresmycina* pertaining to vancoresmycin.

Substrate mycelium is brown-beige on peptone-yeast extract-iron agar, saffron yellow on yeast extract-malt extract agar, and maize yellow on glycerol asparagine, inorganic salts-starch, oatmeal, and tyrosine agars; a brown soluble pigment is formed on yeast extract-malt extract agar. White fragmenting aerial hyphae are produced on inorganic salts-starch, oatmeal, and yeast extract-malt extract agars. Fragmentation of the substrate mycelium is seen on oatmeal and yeast extract-malt extract agars.

Positive for *N*-acetyl-β-glucosamidase, alkaline phosphatase, α-chymotrypsin, cystine arylamidase, esterase (C8), leucine arylamidase, lipase (C14), naphthol-AS-BI-phosphohydrolase, trypsin, and valine arylamidase, but negative for esterase (4), α-fucosidase, α- and β-galactosidases, α-glucosidase, β-glucuronidase, and α-mannosidase (API ZYM tests).

Whole-organism hydrolysates are rich in arabinose and galactose. The fatty acids profile contains major proportions of $C_{16:0}$ iso (41.9%) and smaller proportions (<10%) of $C_{15:0}$ (1.6%), $C_{16:0}$ (1.9%), $C_{17:0}$ (1.8%), $C_{15:1}$ (1.9%), $C_{14:0}$ iso (1.6%), $C_{15:0}$ iso (9.9%), $C_{16:1}$ iso (1.9%), $C_{17:0}$ iso (4.0%), $C_{15:0}$ anteiso (1.1%), $C_{17:0}$ anteiso (4.2%), *cis*9-$C_{16:1}$ (3.0%), $C_{17:1}$ *cis*9 (3.8%), $C_{16:0}$ 10-methyl (2.8%), $C_{16:1}$ 10-methyl (1.4%), $C_{17:0}$ 10-methyl iso (3.3%), $C_{17:0}$ 10-methyl (2.4%), 2-OH-$C_{15:0}$ iso (2.4%), and 2-hydroxy-$C_{16:0}$ iso (8.4%). Additional phenotypic properties are shown in Table 238.

Source: isolated from Indian soil.
DNA G+C content (mol%): not determined.
Type strain: ST 101170, DSM 44592, JCM 12675, NRRL B-24208.
Sequence accession nos: AJ508240 (16S rRNA gene); EU822918 (*gyrB*).

Species *incertae sedis*

1. "**Amycolatopsis lactamdurans**" Barreiro, Pisabarro and Martin 2000, 22

Forms a slight yellow substrate mycelium, a white aerial mycelium and a bright yellow substrate mycelium on modified Bennett's agar supplemented with mannitol and soybean flour. Grows from 25–37°C, but not at 10 or 45°C, and from pH 6.0–9.0.

Allantoin, esculin, and urea are hydrolyzed, but not arbutin. Does not produce H_2S or reduce nitrate. Elastin, hypoxanthine, L-tyrosine, Tween 40, uric acid, xanthine, and xylan are degraded, but not starch. Acid is produced from arabitol, cellobiose, galactose, glucose, glycerol, *myo*-inositol, mannitol, mannose, raffinose, salicin, sorbitol, trehalose, and xylose, but not from adonitol, cellobiose, dulcitol, *meso*-erythritol, glycogen, lactose, maltose, melezitose, melibiose, methyl α-D-glucoside, ribose, sucrose, turanose, or xylitol.

L-Arabinose, D-arabitol, cellobiose, dextrin, glycerol, *myo*-inositol, mannitol, sorbitol, trehalose, xylitol, and xylose are used as sole carbon sources, but not adonitol, *meso*-erythritol, glycogen, lactose, maltose, melezitose, melibiose, methyl α-D-glucoside, raffinose, ribose, or sucrose (all at 1%, w/v). Similarly, citrate, propionate, oxalate, and tartrate are used as sole carbon sources, but not benzoate, lactate, or mucate (all at 0.1%, w/v).

Resistant (μg/ml) to gentamicin sulfate (5), neomycin sulfate (8), streptomycin sulfate (16), novobiocin (10), polymixin B (50), and vancomycin hydrochloride (0.25), but sensitive to penicillin (20) and rifampin (10).

Source: soil.
DNA G+C content (mol%): not determined.
Type strain: ATCC 27382, NRRL 3802.
Sequence accession no. (16S rRNA gene): AJ243301.

Genus VI. **Crossiella** Labeda 2001, 1578^{VP}

DAVID P. LABEDA

Cros.si.el′la. N.L. fem. dim. n. *Crossiella* named for Thomas Cross, a microbiologist at the University of Bradford who made many contributions to actinomycete biology and systematics.

Aerobic. Gram-stain-positive, non-acid fast, nonmotile actinomycetes. Forms branched substrate mycelium (approx. 0.5 μm in diameter) and, on some media, aerial mycelia are produced. **Vegetative mycelium may fragment into rod-shaped elements and sclerotia-like pseudosporangia may be produced on the substrate mycelium. Swellings may be produced at or near the tip of aerial hyphae.** Mycolic acids are absent. Catalase-positive. **Contains *meso*-diaminopimelic acid as the diamino acid and acetylated peptidoglycan. The whole-cell sugar pattern consists of galactose, mannose, rhamnose, and ribose. The phospholipid pattern consists of phosphatidylethanolamine, phosphatidylmethylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. The predominant menaquinone is MK-9(H_4)**. Has a fatty acid profile rich in branched-chain and saturated components. **Phylogenetically, the nearest neighbor is the genus *Kutzneria*.**

DNA G+C content (mol%): 71.4 (T_m).

Type species: **Crossiella cryophila** Labeda 2001, 1579^{VP}.

Further descriptive information

The type species of *Crossiella* was originally described by Takahashi et al. (1986) as *Nocardiopsis mutabilis* subsp. *cryophilis* for a novel soil isolate that produced the antibiotic dopsisamine. The authors observed that the morphological characteristics of the strain were somewhat different from those of *Nocardiopsis* but, based on their chemotaxonomic data, considered that the genus *Nocardiopsis* was the closest fit for their strain. The transfer of *Nocardiopsis mutabilis* and its subspecies to the genus *Saccharothrix* was proposed by two independent studies (Grund and Kroppenstedt, 1989; Labeda and Lechevalier, 1989) based on more detailed chemotaxonomic analyses. Evaluation of DNA relatedness of the type strain of *Nocardiopsis mutabilis* subsp. *cryophilis* with other species within the genus *Saccharothrix* (Labeda and Lechevalier, 1989) demonstrated that it was distinct and therefore constituted a novel species for which the name *Saccharothrix cryophila* was proposed. The DNA relatedness between this strain and strains of the other species was low (2–11%) and there was some question regarding its generic identity. Subsequent phylogenetic analysis of the type strains of many species of the genera within the suborder *Pseudonocardineae*, elevated in this volume to order *Pseudonocardiales*, based on 16S rRNA gene sequences (Labeda and Kroppenstedt, 2000) supported the existence of at least two families, *Actinosynnemataceae* and *Pseudonocardiaceae*, and also demonstrated that a number of *Saccharothrix* species were misclassified. *Saccharothrix cryophilus* is phylogenetically located outside of *Actinosynnemataceae sensu stricto*, far from *Saccharothrix* and closest to the genera *Kutzneria*, *Actinoalloteichus*, and *Streptoalloteichus* as seen in Figure 295. Consideration of the morphological, chemotaxonomic, and phenotypic properties of this strain resulted in the proposal for the creation of the new genus, *Crossiella*, for this species (Labeda, 2001).

Actinomycetes were reported as a significant emergent agent of placentitis and abortion in horses in Kentucky after first being observed in 1986 at the Livestock Disease Diagnostic Center at the University of Kentucky (Donahue and Williams, 2000; Giles et al., 1993; Hong et al., 1993). Nocardioform placentitis is the term used to describe this distinct type of placentitis in horses and the infection is diagnosed based on the location of the lesion on the chorionic surface of the placenta and the recovery of Gram-stain-positive branching micro-organisms upon culture. The actinomycete biomass may infiltrate up to 30% of the surface area of the placenta (light gray area in Figure 296), but does not invade fetal tissue and probably contributes to death or weakening of the unborn foal through competition for nutrients. Infections can result in spontaneous abortions, still birth, full-term deliveries of weak foals, or no apparent effect and healthy foals. The 16S rRNA gene sequences from strains isolated from placental tissues exhibit high similarity (98.1%) to that of the type strain of *Crossiella cryophila* and morphological and chemotaxonomic characteristics are also typical for the genus. Physiological characteristics for all strains are quite similar and 16S rRNA gene sequences are identical. A novel species, *Crossiella equi*, was therefore proposed for these equine isolates (Donahue et al., 2002). The manner in which *Crossiella equi* strains become introduced into the equine uterus and infect the placenta is still unknown, as are possible environmental reservoirs for this species. The incidence of *Crossiella equi* equine placentitis is quite variable and numbers of infected placentas observed are relatively low in most years.

Enrichment and isolation procedures

Crossiella grows well on typical actinomycete growth media such as yeast extract-malt extract agar (Shirling and Gottlieb, 1966) or NZamine medium [DSMZ medium 554 (DSMZ, 2001)]. Strains have been isolated from lesions on equine placentas on tryptic soy agar containing 5% blood, but other media without blood can be used. The type strain of *Crossiella cryophilus* was isolated from dilutions of a soil sample from Shosenkyo, Yamanashi Prefecture, Japan, but details of the isolation procedure are lacking and there have been no other reports of isolation of strains of *Crossiella* from environmental samples.

Maintenance procedures

Working cultures of *Crossiella* can be maintained as refrigerated (4°C) agar slants on an appropriate medium such as yeast extract-malt extract medium (Shirling and Gottlieb, 1966) or NZamine medium (DSMZ medium 554). The slants are generally incubated for 5–7 d at 28–30°C prior to refrigeration and then should be subcultured at monthly intervals. Longer term preservation of strains is best accomplished as frozen stocks in 20% aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques.

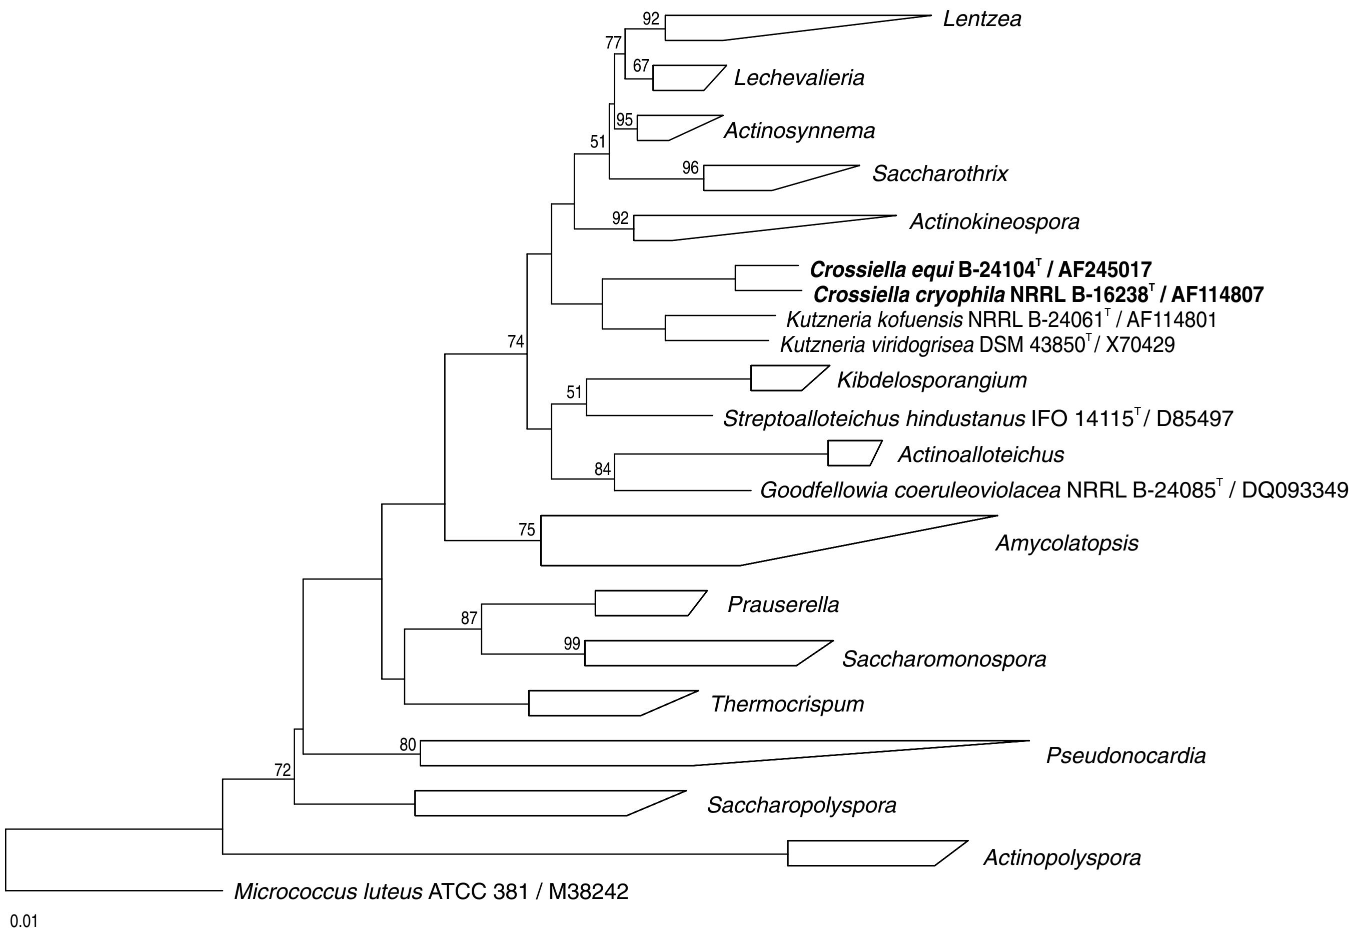

FIGURE 295. Phylogenetic tree for families of the order *Pseudonocardiales*, calculated from almost-complete 16S rRNA gene sequences using Kimura's evolutionary distance methods (Kimura, 1980) and the neighbor-joining method of Saitou and Nei (1987) illustrating the taxonomic position of *Crossiella cryophila* and *Crossiella equi* and the other taxa in the order. Bar = 0.01 nucleotide substitutions per site.

(Printed with permission of N.M. Williams, Livestock Disease Diagnostic Center, University of Kentucky, Lexington, KY, USA.)

Procedures for testing special characters

Strains are routinely cultivated on NZamine medium at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and on NZamine medium.

Chemotaxonomic analyses of strains for polar lipids, menaquinones, and fatty acids are performed using methods previously described by Grund and Kroppenstedt (1989), Minnikin et al. (1984), and Sasser (1990).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, guanine, esculin, hypoxanthine, tyrosine, urea, and xanthine, are typically evaluated using the media of Gordon et al. (1974). Phosphatase activity is evaluated by using the method of Kurup and Schmitt (1973) substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of DSMZ medium 554 and salt tolerance is determined on slants of the same medium supplemented with 4% and 5% NaCl.

Differentiation of the genus *Crossiella* from other genera

The genus *Crossiella* is phylogenetically distinct from neighboring genera based on analyses of 16S rRNA gene sequences (Figure 295). Moreover, the micromorphology of *Crossiella* is distinct from that exhibited by neighboring taxa. *Crossiella* strains exhibit substrate mycelium fragmenting into rod-shaped elements, the presence of sclerotia or pseudosporangium-like bodies on the colony surface (Figure 297), and swellings near the tips of mycelium (Figure 297); the latter two properties have not been observed in members of the genus *Goodfellowiella*. Motile spores have not been observed and true sporangia such as those found in species of the genera *Kutzneria*, *Kibdelosporangium*, and *Streptoalloteichus* are not produced. Chains of spores typical of *Actinoalloteichus* species have not been observed in *Crossiella* species. The chemotaxonomic profile of *Crossiella* species is most similar to that of *Streptoalloteichus* (Table 239), but MK-10(H_4) menaquinones, while present in *Streptoalloteichus*, are not found in *Crossiella* strains.

Differentiation of the species of the genus *Crossiella*

The physiological characteristics of *Crossiella* species are summarized in Table 240. The physiological properties of six strains of *Crossiella equi* were evaluated for the original description of the species and there was some variation observed. Determination of acid production from the various sugars and utilization of organic acids in this species was complicated by the fact that all of the strains tested absorbed the pH indicator dye, bromothymol blue, into their substrate mycelium making it difficult to evaluate test results. The two species can be differentiated by the many physiological differences indicated in Table 240, but most obviously by the lack of growth of *Crossiella cryophila* at temperatures of 37°C or greater. The growth rate of *Crossiella equi* strains is also very much greater than that of *Crossiella cryophila* as well as most other actinomycetes. There are also differences between the fatty acid profiles of the species as can be seen in Table 241.

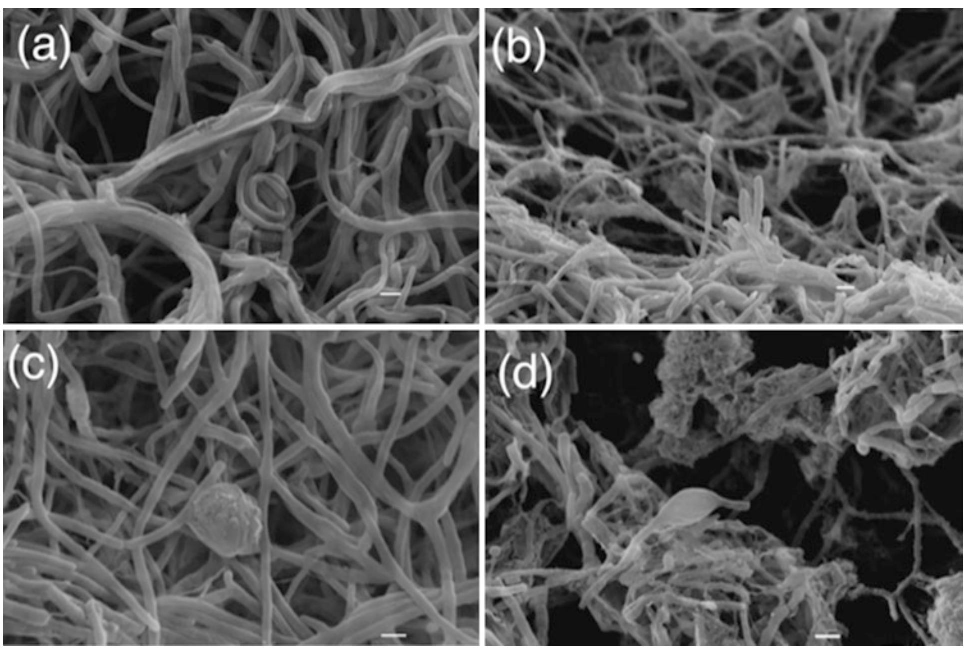

FIGURE 297. Comparison of the micromorphological properties of *Crossiella cryophilus* NRRL B-16238[T] (a, c) and *Crossiella equi* NRRL B-24104[T] (b, d). Note the pseudosporangia on the substrate mycelium in (a) and (b) and the swollen mycelial tips in (c) and (d). Bars = 1 µm.

List of species of the genus *Crossiella*

1. **Crossiella cryophila** (Labeda and Lechevalier 1989) Labeda 2001, 1579[VP] (*Saccharothrix cryophilus* Labeda and Lechevalier 1989, 420; "*Nocardiopsis mutabilis* subsp. *cryophilus*" Takahashi, Hotta, Saito, Morioka, Okami and Umezawa 1986, 179)

cry.o′phi.la. Gr. n. *kruos* icy cold, frost; N.L. adj. *philus* -*a* -*um* (from Gr. adj. *philos* -*ê* -*on*) friend, loving; N.L. fem. adj. *cryophila* cold loving, referring to the low permissive temperature range for growth.

Pale-yellow to light-brown substrate mycelium is produced on most media. White to yellowish-white aerial mycelium is formed, particularly on inorganic salts-starch agar or glycerol-asparagine agar. Soluble pigments are not produced. Physiological properties are shown in Table 240. Temperature range for growth is 10–33°C.

Source: isolated from soil.

DNA G+C content (mol%): 74.1 (T_m).

Type strain: NRRL B-16238, ATCC 51143, DSM 44230, IFO 14475, NBRC 14475, Okami TS-1980.

Sequence accession no. (16S rRNA gene): AF114806.

2. **Crossiella equi** Donahue, Williams, Sells and Labeda 2002, 2172[VP]

e′qui. L. gen. n. *equi* of the horse, referring to the source of isolation of this micro-organism, equine placentas.

Pale orange to light-brown substrate mycelium is formed on most media. Copious white aerial mycelium is produced on most media. Physiological properties are shown in Table 240. Temperature for growth is 10–42°C.

Source: isolated from equine placentas.

DNA G+C content (mol%): 74.1 (T_m).

Type strain: NRRL B-24104, CIP 107800, DSM 44580, LDDC 22291-98.

Sequence accession no. (16S rRNA gene): AF245017.

Genus VII. **Goodfellowiella** Labeda, Kroppenstedt, Euzéby and Tindall 2008, 1048[VP]

David P. Labeda

Good.fel.low.i.el′la. N.L. fem. dim. n. *Goodfellowiella* named for Michael Goodfellow, a microbiologist at the University of Newcastle-upon-Tyne, in recognition of his contributions to microbial systematics.

Aerobic. Gram-stain-positive, non-acid-fast, nonmotile actinomycetes. Branched substrate mycelium (approx. 0.5 µm in diameter) and, on some media, aerial mycelia are produced. **Ovoid conidia are produced by fragmentation of substrate mycelium.** Catalase-positive. **Contains *meso*-diaminopimelic acid as the diamino acid. The whole-cell sugar pattern consists of galactose and ribose. The phospholipid pattern consists of diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylethanolamine with hydroxylated fatty acids, and traces of phosphatidylinositol and phosphatidylinositol mannosides. The predominant menaquinones are MK-9(H_4) and MK-10(H_4). Has a fatty acid profile rich in branched chain and saturated components including 10-methyl-branched heptadecanoic acid and anteiso-branched 2-hydroxy fatty acids.** Phylogenetically, its nearest neighbor is the genus *Actinoalloteichus*.

DNA G+C content (mol%): 68.2 (T_m).

Type species: **Goodfellowiella coeruleoviolacea** (Preobrazhenskaya and Terekhova 1987) Labeda, Kroppenstedt, Euzéby and Tindall 2008, 1048[VP].

Further descriptive information

The type species was originally described by Preobrazhenskaya et al. (1987, 1976) as *Actinomadura coeruleoviolacea* and was subsequently transferred by Kroppenstedt et al. (1990, 1991) to the genus *Saccharothrix* as *Saccharothrix coeruleoviolacea.* During a phylogenetic evaluation of species of the genus *Saccharothrix* with validly published names based on almost complete 16S rRNA gene sequences (Labeda and Kroppenstedt, 2000), it was noted that the type strain of *Saccharothrix coeruleoviolacea* was not related to other species of the genus and represented a new genus within the suborder *Pseudonocardineae*, elevated in this volume to order *Pseudonocardiales*. A polyphasic investigation of the characteristics of this strain demonstrated that it was also chemotaxonomically distinct from *Saccharothrix* and the other genera within the suborder and the new genus *Goodfellowia* was proposed by Labeda and Kroppenstedt (2006). It was later discovered that the genus name *Goodfellowia* had been used previously in as the name of an avian genus and thus *Goodfellowia* Labeda and Kroppenstedt 2006 was taxonomically illegitimate. A proposal was subsequently published to correct this situation by emending the genus name to *Goodfellowiella* (Preobrazhenskaya and Terekhova 1987) Labeda, Kroppenstedt, Euzéby and Tindall 2008.

Maintenance procedures

Working cultures of *Goodfellowiella* can be maintained as refrigerated (4°C) agar slants on appropriate media such as yeast extract-malt extract medium (Shirling and Gottlieb, 1966) or NZamine medium (DSMZ medium 554; DSMZ, 2001). The slants are generally incubated for 5–7 d at 28–30°C prior to refrigeration and then should be subcultured at monthly intervals. Longer term preservation of strains is best accomplished as frozen stocks in 20% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques.

Procedures for testing special characters

Strains are routinely cultivated on NZamine medium at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and NZamine medium.

Chemotaxonomic analyses of strains for fatty acids, menaquinones, and polar lipids are performed using methods described previously by Grund and Kroppenstedt (1989), Minnikin et al. (1984), Saddler et al. (1991), and Sasser (1990).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, guanine, hypoxanthine, tyrosine, xanthine, casein, esculin, urea, and hippurate, are typically evaluated using the media of Gordon et al. (1974). Phosphatase activity is evaluated by using the method of Kurup and Schmitt (1973) substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of DSMZ medium 554 and salt tolerance is determined on slants of the same medium supplemented with 4% and 5% NaCl.

Differentiation of the genus *Goodfellowiella* from other genera

Goodfellowiella coeruleoviolacea is phylogenetically separate from the genus *Saccharothrix*, the genus in which this micro-organism was originally classified, and appears to be most closely related to the genus *Actinoalloteichus*, as can be seen in Figure 298. The chemotaxonomic properties of *Goodfellowiella* distinguish it from *Actinoalloteichus* and the other related taxa within the order *Pseudonocardiales*, as can be seen in Table 242. The whole-cell sugar pattern consisting of only galactose and ribose differs from those of other genera, as does the phospholipid pattern, i.e. a lack of phosphatidylinositol and the presence of both phosphatidyl-

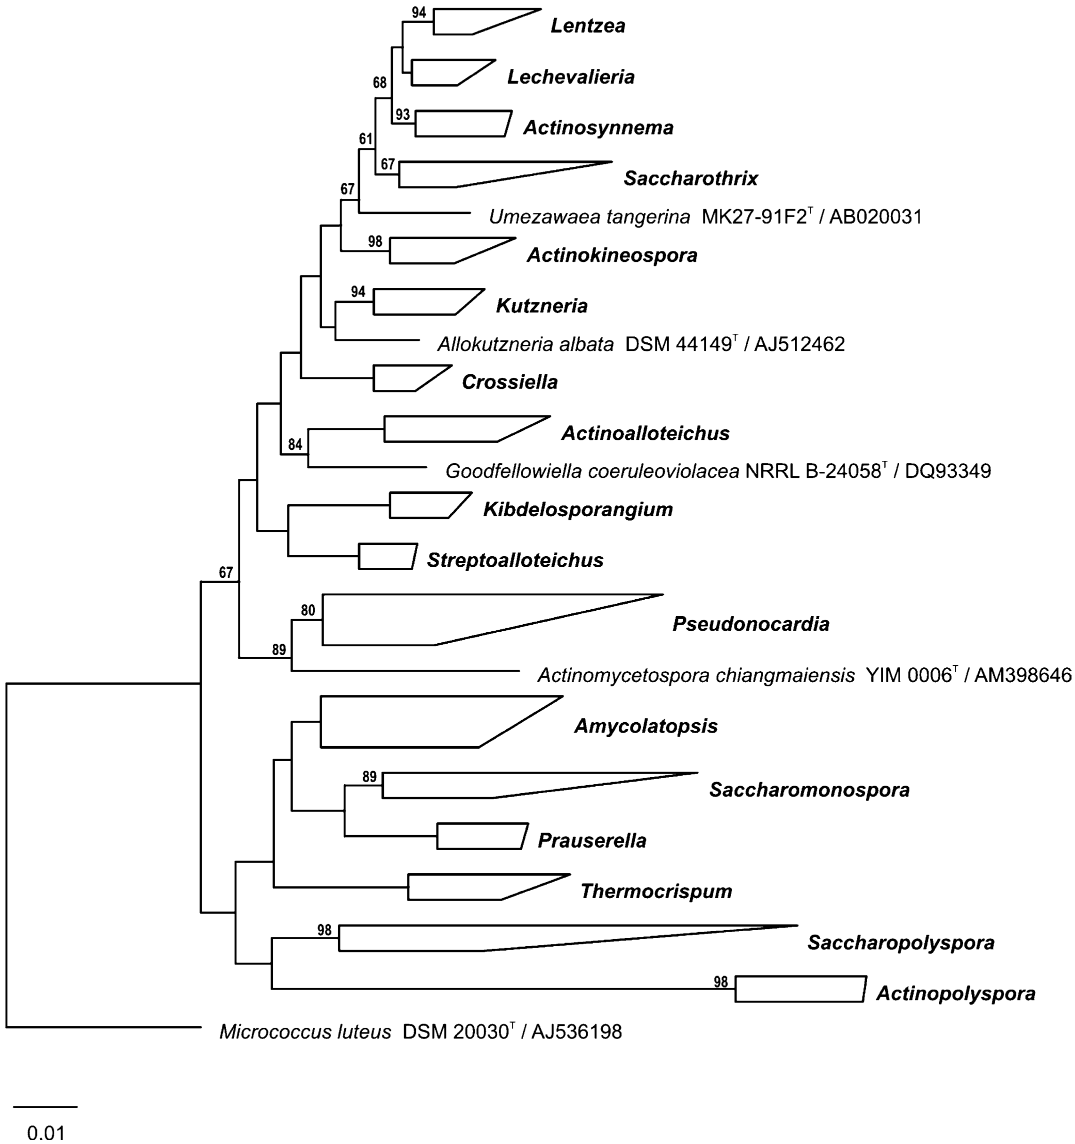

FIGURE 298. Phylogenetic tree for the genera of the order *Pseudonocardiales* calculated from almost-complete 16S rRNA gene sequences using the Kimura's evolutionary distance method (Kimura, 1980) and the neighbor-joining algorithm of Saitou and Nei (1987). Numbers at the nodes represent levels (%) of bootstrap support from 100 resampled datasets; values less than 60% are not shown. Bar = 0.01 nucleotide substitutions per site.

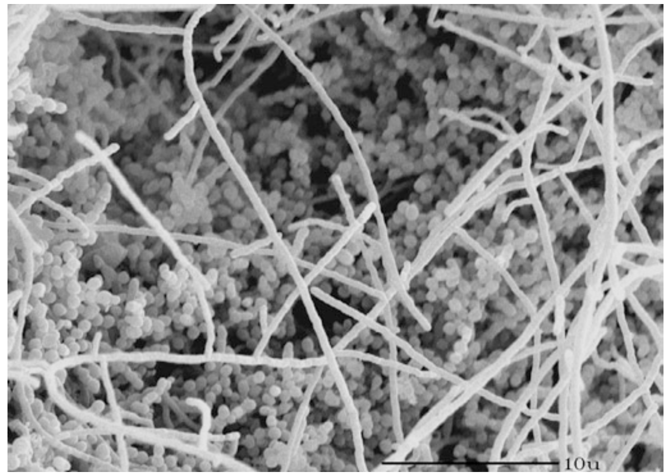

FIGURE 299. Scanning electron micrograph of 21-d growth of *Goodfellowiella coeruleoviolacea* NRRL B-24058^T on yeast extract-malt extract agar. Note that spores are produced by fragmentation of the vegetative mycelium. Bar = 10 μm.

monomethylethanolamine and phosphatidylethanolamine with 2-hydroxy fatty acids. Substantial quantities of menaquinone MK-10(H_4) are present and this is distinct from other taxa within the suborder. The fatty acid profile of *Goodfellowiella coeruleoviolacea* (Table 243) clearly distinguishes it from its nearest phylogenetic neighboring genera by the presence of significant quantities of $C_{17:0}$ 10-methyl fatty acid and various hydroxylated fatty acids. Scanning electron microscopic observations of colony growth on several different media have not revealed the presence of sporangia and the substrate mycelium appears to fragment into coccoidal rod elements (Figure 299). Spore chains typical of those observed in *Actinoalloteichus* species were not observed.

List of species of the genus *Goodfellowiella*

1. **Goodfellowiella coeruleoviolacea** (Preobrazhenskaya and Terekhova 1987) Labeda, Kroppenstedt, Euzeby and Tindall 2008, 1048^{VP} [*Actinomadura coeruleoviolacea* Preobrazhenskaya and Terekhova 1987, 179; *Saccharothrix coeruleoviolacea* (Preobrazhenskaya and Terekhova 1987) Kroppenstedt, Stackebrandt and Goodfellow 1990, 179; illegitimate synonym *Goodfellowia coeruleoviolacea* (Preobrazhenskaya and Terekhova 1987) Labeda and Kroppenstedt 2006, 1206]

co.e.ru.le.o.vi.o.la′ce.a. L. adj. *coeruleus* dark-colored, dark blue; L. adj. *violaceus* violet-colored, violet; N.L. fem. adj. *coeruleoviolacea* dark violet-colored.

Vegetative mycelium is pale yellow to dark brownish-yellow, depending on medium; white aerial hyphae are produced on most media becoming blue in color on several media including inorganic salts-starch (ISP4) agar and yeast extract-malt extract (ISP2) agar. Pale violet soluble pigment is produced on inorganic salts-starch agar and blue-green soluble pigment is produced on yeast extract-malt extract agar. Degrades or hydrolyzes casein, esculin, gelatin, hypoxanthine, starch, tyrosine, and urea. Does not degrade adenine, allantoin, or xanthine. Weakly reduces nitrates. Assimilates acetate, citrate, malate, oxalate, propionate, and succinate; does not assimilate benzoate, lactate, mucate, or tartrate. Acid is produced from adonitol, arabinose, cellobiose, dextrin, erythritol, fructose, galactose, glucose, glycerol, inositol, lactose, maltose, mannitol, mannose, melibiose, methyl α-D-glucoside, methyl β-xyloside, raffinose, rhamnose, salicin, sorbitol, sucrose, trehalose, and xylose; no acid is produced from dulcitol or melezitose. Grows weakly in the presence of 4% NaCl and not at all at higher salt concentrations.

Temperature range for growth is 15–45°C, with optimum growth around 30°C.

Source: isolated from soil.

DNA G+C content (mol%): 68.2 (T_m).

Type strain: NRRL B-24058, DSM 43935, INA 3564, JCM 9110, NBRC 14988, VKM Ac-1083.

Sequence accession no. (16S rRNA gene): DQ093349.

Genus VIII. **Kibdelosporangium** Shearer, Colman, Ferrin, Nisbet and Nash 1986a, 48[VP]

David P. Labeda

Kib.del.o.spo.ran′gi.um. Gr. adj. *kibdelos* false, ambiguous; Gr. n. *spora* seed, and in biology a spore; Gr. n. *angeion* a vessel; N.L. neut. n. *Kibdelosporangium* false or ambiguous sporangium.

Aerobic, catalase-positive, Gram-stain-positive, non-acid-fast, filamentous organisms that produce a substrate mycelium that penetrates the agar and forms a compact layer on top of the agar; aerial mycelium originates from the substrate mycelium. **Substrate mycelium may exhibit varying degrees of fragmentation and usually bears specialized structures that appear to be dichotomously branched, septate hyphae radiating from a common stalk. The aerial mycelia bear long chains of spores and sporangium-like structures. The sporangium-like structures are surrounded by well-defined walls, but do not contain spores and germinate directly, producing one or more germ tubes when placed on solid growth media. Motile elements or spores are not present. Contains *meso*-diaminopimelic acid as the diamino acid. Whole-cell sugar pattern consists of arabinose and D-galactose, with traces of madurose usually present**. The phospholipid pattern consists of diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, phosphatidylinositol mannosides, and phosphatidylmethylethanolamine. **Mycolic acids are not present**.

DNA G+C content (mol%): 66 (T_m).

Type species: **Kibdelosporangium aridum** Shearer, Colman, Ferrin, Nisbet and Nash 1986a, 48[VP].

Further descriptive information

The genus *Kibdelosporangium* is placed phylogenetically within the family *Pseudonocardiaceae* in the order *Pseudonocardiales* (Figure 298) based on 16S rRNA gene sequences and shares similar chemotaxonomic characteristics with many of the genera within the family. The reproductive structures of members of the genus are quite distinct, however, and *Kibdelosporangium* colonies are frequently covered with straight to flexuous chains of rod-shaped spores (Figure 300) when viewed microscopically from above. Sporangium-like structures are observed beneath the spore chains, closer to the substrate mycelium (Figure 301). The sporangium-like structures and the spore chains can arise from the same aerial hyphae and may be borne apically on branched or unbranched hyphae, as well as terminally on short lateral hyphal branches.

The sporangium-like structures originate as small round swellings at the tips of the hyphae that continue to enlarge and, at maturity, are usually 9 to 35 µm in diameter (Figure 302). They are surrounded by a well-defined sporangial wall and contain septate, branched hyphae in an amorphous matrix (Figure 303). When placed on a suitable growth medium, the sporangium-like bodies germinate, usually within 24 to 48 h, and produce one or more germ tubes.

A third species, *Kibdelosporangium albatum*, was described by Tomita and others in 1993 because it appeared morphologically and chemotaxonomically most similar to the described members of the genus *Kibdelosporangium* (Tomita et al., 1993). This species has now been transferred by Labeda and Kroppenstedt (2008) to the new genus *Allokutzneria* as *Allokutzneria albata* on the basis of the phylogenetic position of this species, nearest to the genus *Kutzneria*, and its unique chemotaxonomic characteristics.

Enrichment and isolation procedures

Kibdelosporangium species can be isolated from soil by plating serial dilutions of the samples on starch-casein-nitrate agar (Küster and Williams, 1964) or arginine-glycerol-salt agar (El-Nakeeb and Lechevalier, 1963) media supplemented with

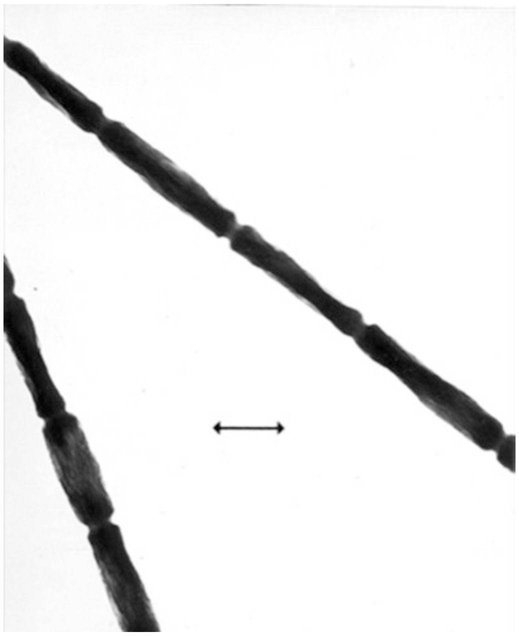

FIGURE 300. Transmission electron micrograph of *Kibdelosporangium aridum* spore chains (19-d-old culture on Bennett's agar). Bar = 1 µm. (Reproduced with permission from Shearer et al., 1986a. Int. J. Syst. Bacteriol. *36*: 47–54.)

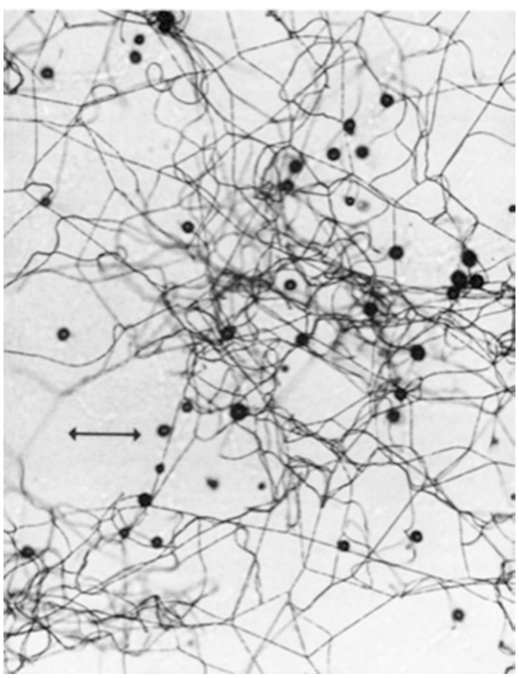

FIGURE 301. Micrograph of aerial mycelium with long, irregularly curved chains of spores and, nearer the agar surface, sporangium-like structures (*Kibdelosporangium aridum*; 26-d culture on water agar). Bar = 55 µm.

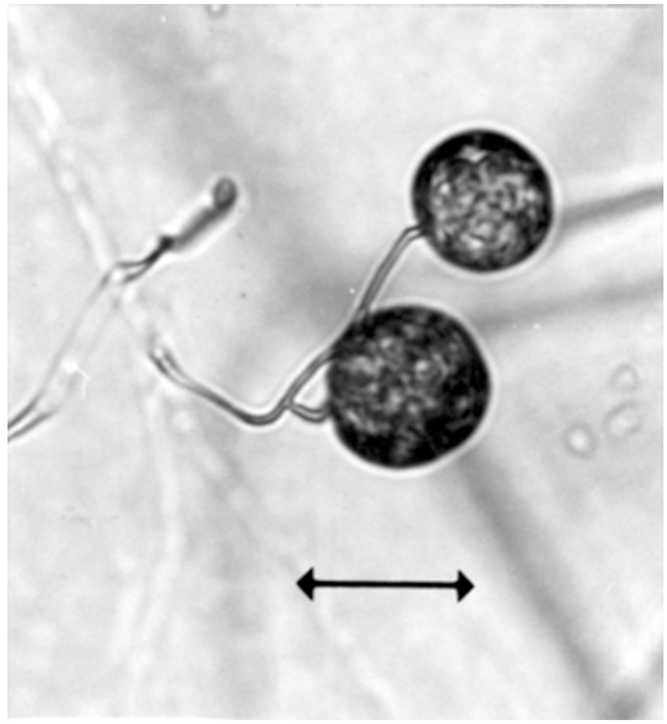

FIGURE 302. Micrograph of sporangium-like structures of *Kibdelosporangium aridum* (8-week-old culture on water agar). Bar = 14 µm. (Reproduced with permission from Shearer et al., 1986a. Int. J. Syst. Bacteriol. *36*: 47–54.)

FIGURE 303. Transmission electron micrograph of thin section of sporangium-like structure of *Kibdelosporangium aridum* (2.5-week-old culture on thin potato-carrot agar). Bar = 1.2 µm. (Reproduced with permission from Shearer et al., 1986a. Int. J. Syst. Bacteriol. *36*: 47–54.)

either vancomycin (1–25 μg/ml) or gentamicin (2.5–5.0 μg/ml) and antifungal antibiotics (e.g. cycloheximide, 25 μg/ml) (Shearer, 1987). Pre-treating air-dried soil samples by heating at 120°C for 60 min may also prove helpful by eliminating many competing soil micro-organisms. Plates are routinely incubated at 28°C for 4 weeks.

Kibdelosporangium colonies resemble those of many other actinomycetes and are therefore not easily identified on isolation plates. Observation of sporulating colonies on isolation plates microscopically (400×) is the best method to identify typical *Kibdelosporangium* colonies on these plates.

Maintenance procedures

Serial transfer of strains is not an acceptable method of maintenance for *Kibdelosporangium* species because they tend to lose the ability to produce sporangium-like structures after several transfers. Moderate to long-term preservation of strains is best accomplished as frozen stocks in 10% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques.

Procedures for testing special characters

Strains are routinely cultivated on yeast extract-malt extract (ISP2) agar at 30°C. Morphological observations are made on the media of Shirling and Gottlieb (1966), thin potato-carrot agar (Higgins et al., 1967), soil extract agar (Shearer et al., 1983), or tap water agar.

Chemotaxonomic analysis of strains for fatty acids, menaquinones, and polar lipids are performed using the previously described methods of Grund and Kroppenstedt (1989), Minnikin et al. (1984), Sasser (1990), and Saddler et al. (1991).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, guanine, hippurate, hypoxanthine, tyrosine, xanthine, and urea, are typically evaluated using the media of Gordon et al. (1974). Phosphatase activity is determined by using the method of Kurup and Schmitt (1973) substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of DSMZ medium 554 (DSMZ, 2001) and salt tolerance is determined on slants of the same medium supplemented with 2 to 8% NaCl.

Differentiation of the genus *Kibdelosporangium* from other genera

Species of the genus *Kibdelosporangium* can be easily differentiated from the other sporangium- and pseudosporangium-forming genera within the order *Pseudonocardiales*, where they are firmly placed on the basis of 16S rRNA gene phylogeny (Figure 298), as well as on morphological and chemotaxonomic criteria. All *Kibdelosporangium* species produce sporangium-like bodies that do not appear to contain spores, similar to *Allokutzneria*, but are different from *Kutzneria* species whose sporangia do contain spores, see Table 244. Both *Kibdelosporangium* and *Allokutzneria* produce chains of spores on their aerial hyphae, but this is not observed in *Kutzneria* species. The chemotaxonomic profile for *Kibdelosporangium* species is also different from the other sporangiate or pseudosporangiate genera within the order, as can be seen in Table 244.

Differentiation of the species of the genus *Kibdelosporangium*

The physiological characteristics of *Kibdelosporangium* species and subspecies are summarized in Table 245 and can be used to differentiate between them. The strains are phylogenetically distinct based on 16S rRNA gene sequences (Figure 304) and gross colonial morphology provides some additional information for differentiation between the *Kibdelosporangium aridum* subspecies and *Kibdelosporangium philippinense*.

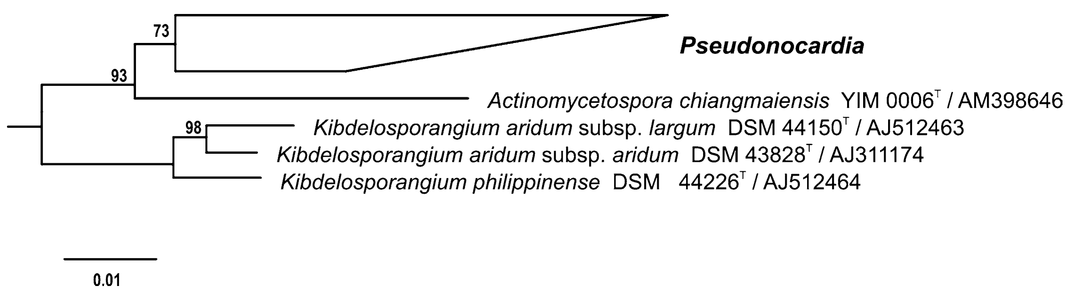

FIGURE 304. Phylogenetic tree for the genera *Kibdelosporangium*, *Actinomycetospora*, and *Pseudonocardia* calculated from almost-complete 16S rRNA gene sequences using the Kimura's evolutionary distance method (Kimura, 1980) and the neighbor-joining algorithm of Saitou and Nei (1987). Percentages at the nodes represent levels of bootstrap support (Felsenstein, 1993) from 100 resampled datasets; values less than 60% are not shown. Bar = 0.01 nucleotide substitutions per site.

List of species of the genus *Kibdelosporangium*

1. **Kibdelosporangium aridum** Shearer, Colman, Ferrin, Nisbet and Nash 1986a, 48[VP]

a′ri.dum. L. neut. adj. *aridum* dry, arid.

The substrate mycelium is off-white to grayish yellow-brown in color and is well developed with moderately branching, septate hyphae that are 0.4–1.0 µm in diameter. Fragmentation of substrate hyphae without hyphal displacement frequently occurs in plate cultures. Characteristic crystals are produced in the agar on many media. No pigments other than melanin or yellow-brown soluble pigments are produced. Produces the glycopeptides antibiotics aridicins A, B, and C (Shearer et al., 1985; Sitrin et al., 1985). Temperature for growth is 30°C.

Source: isolated from soil.

DNA G+C content (mol%): 66 (T_m).

Type strain: ATCC 39323, DSM 43828, JCM 7912, NBRC 14493, NRRL B-16436, SK&F AAD-216, VKM Ac-1316.

Sequence accession no. (16S rRNA gene): AJ311174.

Subsequently this species has been divided into subspecies.

1a. **Kibdelosporangium aridum subsp. aridum** Shearer, Colman, Ferrin, Nisbet and Nash 1986a, 48[VP]

The description is as for the species.

Type strain: ATCC 39323, DSM 43828, JCM 7912, NBRC 14493, NRRL B-16436, SK&F AAD-216, VKM Ac-1316.

Sequence accession no. (16S rRNA gene): AJ311174.

1b. **Kibdelosporangium aridum subsp. largum** Shearer, Giovenella, Grappel, Hedde, Mehta, Oh, Pan, Pitkin and Nisbet, 1988, 136[VP] (Effective publication: Shearer, Giovenella, Grappel, Hedde, Mehta, Oh, Pan, Pitkin and Nisbet 1986b, 1391.)

lar′gum. L. neut. adj. *largum* abundant, plentiful, numerous.

The substrate mycelium is off-white to yellow-brown in color and shows branching. The aerial mycelium is white to light gray in color, when produced. Pale yellow-brown to yellow-brown soluble pigments are produced on some media. Characteristic crystals are formed in the agar on some media. Temperature for growth is 30°C. Produces the glycopeptides antibiotics aridicins A, B, and C (Shearer et al., 1985; Sitrin et al., 1985) and the kibdelins A, B, C, and D (Folena-Wasserman et al., 1986; Shearer et al., 1986b).

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: ATCC 39922, DSM 44150, JCM 9107, NBRC 15152, SK&F AAD-609.

Sequence accession no. (16S rRNA gene): AJ512463.

2. **Kibdelosporangium philippinense** Mertz and Yao 1988, 286[VP]

phil.ip.pi.nen′se. N.L. neut. adj. *philippinense* pertaining to the Philippines.

The branching substrate mycelium is generally pale yellow to orange-yellow in color. Aerial mycelium is white in color, when produced. Light brown to light reddish-brown soluble pigments are formed on some growth media. Production of crystals is not observed on any growth medium. Produces a ristocetin-like glycopeptide antibiotic. Temperature for growth is 30°C.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: A80407, ATCC 49844, DSM 44226, JCM 9918, NBRC 15154, NRRL 18198.

Sequence accession no. (16S rRNA gene): AJ512464.

Genus IX. **Kutzneria** Stackebrandt, Kroppenstedt, Jahnke, Kemmerling and Gürtler 1994, 267[VP]

David P. Labeda

Kutz.ne′ri.a. N.L. fem. n. *Kutzneria* named after Hans-Jürgen Kutzner, a German microbiologist.

Aerobic, Gram-stain-positive, mesophilic actinomycete which forms a stable, branched, cottony aerial mycelium. **Globose sporangia are large (diameter of 10–48 μm).** Sporangial walls are thick and strong. **Sporangiophores more than 50 μm long are formed by septation of coiled, unbranched hyphae within sporangiophores. Spores are spherical, rod-shaped, or ovoid and nonmotile.** Some species are thermotolerant. Chemo-organotrophic. **Cell walls contain *N*-acetylated muramic acid**, ***meso*-diaminopimelic acid, and generally galactose as the characteristic sugar.** Rhamnose may also be present as a whole-cell diagnostic sugar. **MK-9(II, III-H_4) are the major menaquinones. Major phospholipids include diphosphatidylglycerol, hydroxyphosphatidylethanolamine, phosphatidylethanolamine, and phosphatidylinositol. Major fatty acids are $C_{16:0}$ iso, $C_{16:0}$ iso 2-OH, $C_{16:0}$ 10-methyl, $C_{17:0}$ anteiso, and $C_{17:0}$ 2-OH anteiso; $C_{10:0}$, $C_{14:0}$ iso, and $C_{14:0}$ fatty acids are absent.** Natural habitat is soil.

DNA G+C content (mol%): 70.3–70.7 (T_m).

Type species: **Kutzneria viridogrisea** (Okuda, Furumai, Watanabe, Okugawa and Kimura 1966) Stackebrandt, Kroppenstedt, Jahnke, Kemmerling and Gürtler 1994, 268[VP].

Further descriptive information

All of the species currently classified within the genus *Kutzneria* were originally described as *Streptosporangium* species with validly published names based on their production of sporangia (Figure 305). The sporangia are produced on long sporophores (Figure 306) containing chains of nonmotile spores (Figure 307). Stackebrandt et al. (1994) proposed that these species be transferred to the new genus *Kutzneria* because phylogenetic analysis based on 16S rRNA genes (Kemmerling et al., 1993), as well as previous phylogenetic studies based on 5S rRNA genes (Kudo et al., 1993) and electrophoretic mobility of ribosomal protein AT-L30 (Ochi and Miyadoh, 1992), demonstrated that they were phylogenetically distinct from species of the genus *Streptosporangium*, as can be seen by their phylogenetic position within the suborder *Pseudonocardineae*, now the order *Pseudonocardiales*, shown in Figure 277 in the treatment of the family *Pseudonocardiaceae*. The chemotaxonomic characteristics of the species transferred to *Kutzneria* were also observed to be distinct from those of *Streptosporangium sensu stricto*, as can be seen in Table 246, particularly with regard to the lack of madurose in the whole-cell sugar pattern, the lack of ninhydrin-positive and sugar-positive phospholipids in their polar lipid patterns, and major differences in fatty acid and menaquinone profiles.

Enrichment and isolation procedures

Nonomura and Ohara (1969a) described a novel method for the isolation of *Microbispora* and *Streptosporangium* from soil

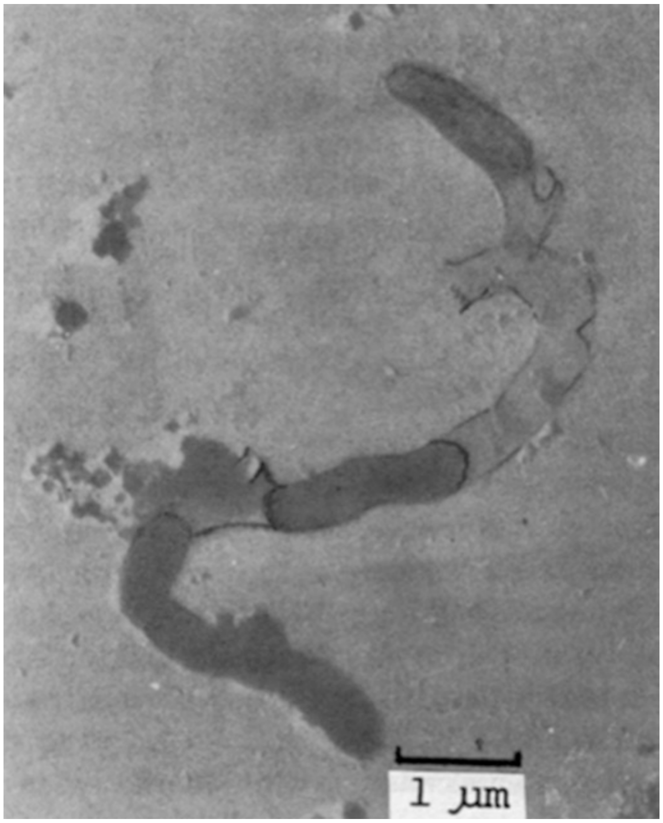

FIGURE 307. Electron micrograph showing *Kutzneria kofuensis* sheathed spores from within the sporangium. (Reproduced with permission from Nonomura and Ohara, 1969b. J. Ferment. Technol. *47*: 648.)

samples; the type strain of *Kutzneria kofuensis* was isolated using this procedure. Soil samples are pretreated by air drying, grinding in a mortar, and then heating at 120°C for 1 h. Aliquots of serial dilutions of the soil samples are spread onto the surface of arginine-vitamin (AV) agar typically containing antifungal antibiotics (e.g. cycloheximide and/or nystatin at 50 µg/ml) and plates are incubated for 40 d at 30°C. AV agar consists of (per l): L-arginine hydrochloride, 0.3 g; glucose, 1.0 g; glycerol, 1.0 g; K_2HPO_4, 0.3 g; $MgSO_4 \cdot 7H_2O$, 0.2 g; NaCl, 0.3 g; thiamine hydrochloride, 0.5 mg; riboflavin, 0.5 mg; niacin, 0.5 mg; pyridoxine hydrochloride, 0.5 mg; inositol, 0.5 mg; calcium pantothenate, 0.5 mg; *p*-aminobenzoic acid, 0.5 mg; biotin, 0.25 mg; $Fe_2(SO_4)_3$, 10 mg; $CuSO_4 \cdot 5H_2O$, 1 mg; $MnSO_4 \cdot H_2O$, 1 mg; $ZnSO_4 \cdot 7H_2O$, 1 mg; agar, 15 g. The pH should be adjusted to 6.4 prior to sterilization. The vitamins should be filter-sterilized and added to autoclaved and tempered medium prior to dispensing.

Maintenance procedures

Working cultures of *Kutzneria* can be maintained as refrigerated (4°C) agar slants on appropriate medium such as NZamine agar (DSMZ medium 554; DSMZ, 2001). The slants are generally incubated for 5–7 d at 28–30°C prior to refrigeration and then should be subcultured at monthly intervals. Longer term preservation of strains is best accomplished as frozen stocks in 20% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques. Strains have also been successfully stored for shorter periods as quick-frozen stationary-phase broth cultures or mycelium suspensions in 20% aqueous glycerol at −20 to −72°C.

Procedures for testing special characters

Strains are routinely cultivated on NZamine agar at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and NZamine agar.

Chemotaxonomic analysis of strains for fatty acids, menaquinones, and polar lipids are performed using methods previously described by Grund and Kroppenstedt (1989), Minnikin et al. (1984), Sasser (1990), and Saddler et al. (1991). Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, guanine, hippurate, hypoxanthine, tyrosine, xanthine, and urea, are typically evaluated using the media of Gordon et al. (1974). Phosphatase activity is determined by using the method of Kurup and Schmitt (1973), but substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of DSMZ medium 554 and salt tolerance is determined on slants of the same medium supplemented with 4% and 5% NaCl.

Differentiation of the genus *Kutzneria* from other genera

The genus *Kutzneria* is phylogenetically distinct from all of the other sporangium- or pseudosporangium-forming genera within the suborder *Pseudonocardineae*, now the order *Pseudonocardiales*, but is phylogenetically most closely related to the genus *Allokutzneria*, as can be seen in Figure 308. The morphology of the sporangia produced by *Kutzneria* species and their chemotaxonomic characteristics (Table 246) differentiate them from similar sporangium-producing genera. The chemotaxonomy of the genus *Kutzneria* is distinct from that of *Allokutzneria* in containing galactose and mannose as whole-cell sugars, i.e. arabinose, galactose, and mannose versus galactose and rhamnose that are found in *Allokutzneria*. The phospholipid profiles of these two genera are also quite different: *Allokutzneria* contains *lyso*-phosphatidylethanolamine, *lyso*-phosphatidylmethylethanolamine, and phosphatidylethanolamine containing hydroxylated fatty acids, whereas these are absent in *Kutzneria*. The sporangial morphology and chemotaxonomic profile, particularly in regard to the whole-cell sugar pattern and predominant menaquinones, between *Kutzneria* and *Kibdelosporangium*, are also quite different, as can be seen in Table 246.

Differentiation of the species of the genus *Kutzneria*

The morphological and physiological characteristics of *Kutzneria* species are summarized in Table 247 and can be used to differentiate between species, although a common set of physiological tests has not been used in the description of all species. The whole-cell sugar patterns of each species also appear to be distinct. The strains can also be distinguished based on their 16S rRNA gene sequences and phylogeny (Figure 308).

List of species of the genus *Kutzneria*

1. **Kutzneria viridogrisea** (Okuda, Furumai, Watanabe, Okugawa and Kimura 1966) Stackebrandt, Kroppenstedt, Jahnke, Kemmerling and Gürtler 1994, 268[VP] (Basonym: *Streptosporangium viridogriseum* Okuda, Furumai, Watanabe, Okugawa and Kimura 1966, 126.)

vi.ri.do.gri′se.a. L. adj. *viridis* green; N.L. adj. *griseus* gray; N.L. fem. adj. *viridogrisea* greenish gray.

Substrate mycelium is yellowish-brown in color on most growth media. Cottony aerial mycelium is produced, initially white in color, then becoming greenish-gray to olive-gray, depending upon the growth medium. Soluble pigments are not produced on any medium. Temperature range for growth is 17–45°C, with an optimum at 37°C. Whole-cell sugars are galactose and rhamnose. Produces sporoviridin.

Source: isolated from soil.

DNA G+C content (mol%): 70.3 (HPLC).

Type strain: ATCC 25242, DSM 43850, JCM 3282, NBRC 15561, NRRL B-24059, VKM Ac-1297.

Sequence accession no. (16S rRNA gene): U58530.

2. **Kutzneria albida** (Furumai, Ogawa and Okuda 1968) Stackebrandt, Kroppenstedt, Jahnke, Kemmerling and Gürtler 1994, 268[VP] (Basonym: *Streptosporangium albidum* Furumai, Ogawa and Okuda 1968, 174)

al′bi.da. L. fem. adj. *albida* white.

Substrate mycelium is colorless to yellowish-brown on synthetic media with production of thin white aerial mycelia which become cottony or floccose and brownish-white. Sporangia (10–30 µm) can be easily observed microscopically. Substrate mycelium is pale yellow to reddish-brown on organic media. Soluble pigments are not produced on any medium. Temperature range for growth is 17°C to 45°C with an optimum at 37°C. Whole-cell sugar is rhamnose. Produces the antibiotic sporoviridin.

Source: isolated from soil.

DNA G+C content (mol%): 70.3 (HPLC).

Type strain: ATCC 25243, DSM 43870, JCM 3240, NBRC 13901, NRRL B-24060.

Sequence accession no. (16S rRNA gene): EF543522.

3. **Kutzneria kofuensis** (Nonomura and Ohara 1969b) Stackebrandt Kroppenstedt, Jahnke, Kemmerling and Gürtler 1994, 268[VP] (Basonym: *Streptosporangium viridogriseum* subsp. *kofuense* Nonomura and Ohara 1969b, 708)

ko.fu.en′sis. N.L. fem. adj. *kofuensis* belonging to Kofu, a district in Japan, where the organism was isolated.

Grows well on oatmeal-yeast extract-glucose agar and yeast-malt agar. Aerial mycelium is greenish-gray. Soluble pigments are not produced on any medium. Temperature range for growth is 17–45°C, with an optimum at 37°C. Whole-cell sugars are rhamnose and galactose. Produces chloramphenicol.

Source: isolated from soil.

DNA G+C content (mol%): 70.3 (HPLC).

Type strain: ATCC 27102, DSM 43851, JCM 3157, NBRC 13989, NRRL B-24061.

Sequence accession no. (16S rRNA gene): AF114801.

Genus X. **Lechevalieria** Labeda, Hatano, Kroppenstedt and Tamura 2001, 1049[VP]

David P. Labeda

Le.che.va.li.e′ri.a. N.L. fem. n. *Lechevalieria* named after the American microbiologists Hubert and Mary Lechevalier, who contributed substantially to the field of actinomycete biology during their careers at the Waksman Institute of Microbiology.

Branching vegetative mycelium (approx. 0.5 µm in diameter) is produced. **Very scant aerial mycelium is formed on some media.** Gram-stain-positive. Lysozyme resistant. Catalase-positive and aerobic. **The cell wall contains *meso*-diaminopimelic acid as the diamino acid. Whole-cell sugar pattern consists of galactose, mannose, and traces of rhamnose. Phospholipid pattern consists of significant quantities of phosphatidylethanolamine lacking hydroxylated fatty acids, as well as diphosphatidylglycerol, phosphatidylglycerol, and**

phosphatidylinositol. The major menaquinone is MK-9(H_4). Fatty acid profile consists of saturated and mono-unsaturated iso and anteiso fatty acids. **Phylogenetically represents a line of descent in the family *Pseudonocardiaceae*; adjacent to the genus *Saccharothrix* and close to the genera *Actinosynnema* and *Lentzea*. 16S rRNA gene sequence contains genus-specific diagnostic nucleotide signature pattern of TT (844–845) and GGT (1107–1109).**

DNA G+C content (mol%): 68–71.4 (T_m).

Type species: **Lechevalieria aerocolonigenes** (Shinobu and Kawato 1960) Labeda, Hatano, Kroppenstedt, and Tamura 2001, 1050[VP].

Further descriptive information

The genus *Lechevalieria* was described by Labeda et al. (2001) to contain strains formerly placed in the genus *Saccharothrix* that were found to be distinct by phylogenetic analysis of 16S rRNA gene sequences. Both of the constituent species, *Lechevalieria aerocolonigenes* and *Lechevalieria flava*, had been transferred previously into *Saccharothrix* from the genera *Streptomyces* and *Nocardiopsis*, respectively, although the latter taxon had been previously transferred first from the genus *Actinomadura* to the genus *Nocardiopsis*. Previously, the classification of these organisms had been based largely on morphology and then on chemotaxonomy. Subsequent phylogenetic analyses based on 16S rRNA gene sequences elucidated the significance of new chemotaxonomic markers which are essential for distinguishing *Lechevalieria* species from neighboring taxa.

Enrichment and isolation procedures

Lechevalieria strains, as well as those of the genera *Lentzea* and *Saccharothrix*, can be isolated from soil and plant residue samples by spreading soil dilutions onto the surface of routine media used for the general isolation of actinomycetes, such as 1.5% crude agar and 0.4% casein hydrolysate in tap water. Antibiotics can be used to more selectively isolate members of these genera as has been described by Shearer (1987). The recently described species *Lechevalieria fradiae* and *Lechevalieria xinjiangensis* were isolated from soil samples by serial plating on yeast extract-malt extract agar (Shirling and Gottlieb, 1966) and modified Bennett's agar (Jones, 1949), respectively.

Maintenance procedures

Working cultures of *Lechevalieria* can be maintained as refrigerated (4°C) agar slants on appropriate medium such as NZamine agar (DSMZ medium 554; DSMZ, 2001). The slants are generally incubated for 5 to 7 d at 28–30°C prior to refrigeration and then should be subcultured at monthly intervals. Longer term preservation of strains is best accomplished as frozen stocks in 20% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques. Strains have also been successfully stored for shorter periods as quick-frozen stationary-phase broth cultures or mycelium suspensions in 20% aqueous glycerol at −20 to −72°C.

Procedures for testing special characters

Strains are routinely cultivated on NZamine agar (DSMZ medium 554) at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and NZamine agar.

Chemotaxonomic analysis of strains for fatty acids, menaquinones, and polar lipids are performed using methods described previously by Grund and Kroppenstedt (1989), Minnikin et al. (1984), Sasser (1990), and Saddler et al. (1991).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, guanine, hippurate, hypoxanthine, tyrosine, xanthine, and urea, are typically evaluated using the media of Gordon et al. (1974). Phosphatase activity is determined by using the method of Kurup and Schmitt (1973) substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of DSMZ medium 554 and salt tolerance on slants of the same medium supplemented with 4% and 5% NaCl.

Differentiation of the genus *Lechevalieria* from other genera

The type strains of *Lechevalieria aerocolonigenes*, *Lechevalieria flava*, *Lechevalieria fradiae*, and *Lechevalieria xinjiangensis* form a monophyletic lineage distinct from the genus *Lentzea* (mean nucleotide similarity of 96.7%), and intermediary between *Lentzea* and the genus *Actinosynnema* (mean nucleotide similarity of 97.3%) as can be seen in Figure 290. The aligned sequences of the 16S rRNA genes for *Lechevalieria*, *Actinosynnema*, *Lentzea*, and *Saccharothrix* (Figure 309) illustrate that *Lechevalieria* strains can be clearly distinguished from the other genera on the basis of the diagnostic nucleotide signatures TT (844–845) and GGT (1107–1109). Note that the published 16S rRNA gene sequence for *Lechevalieria fradiae* contains the signature GGC (1107–1109) and this has not yet been confirmed to be accurate.

Species of the genus *Lechevalieria* can be distinguished from the genera *Actinosynnema* and *Saccharothrix* by the lack of hydroxy-substituted fatty acids in the phosphatidylethanolamine component of the diagnostic phospholipids (see Table 248), similar to species of the genus *Lentzea*. *Lechevalieria*, *Saccharothrix*, and *Umezawaea* strains tend to contain varying amounts of rhamnose in whole-cell hydrolysates, whereas *Lentzea* strains are observed to totally lack or contain only trace amounts of rhamnose and may also contain ribose. *Actinosynnema* species have only galactose and mannose as their diagnostic whole-cell sugar pattern.

Lechevalieria strains produce very sparse aerial mycelium on agar media, their substrate mycelium fragments into coccoid to coccoidal-rod-shaped elements, and they have not been observed to produce sporangia, coremia, or motile spores, which differentiates them from the genera *Actinokineospora* and *Actinosynnema*.

Differentiation of the species of the genus *Lechevalieria*

The physiological characteristics of *Lechevalieria* species are summarized in Table 249 and can be used to differentiate between species, although a common set of physiological tests has not been used in the description of all species. Gross colonial morphology provides some additional information for differentiation

List of species of the genus *Lechevalieria*

1. **Lechevalieria aerocolonigenes** (Shinobu and Kawato 1960) Labeda, Hatano, Kroppenstedt and Tamura 2001, 1050[VP] [*Saccharothrix aerocolonigenes* (Shinobu and Kawato 1960) Labeda 1986, 109; *Streptomyces aerocolonigenes* Shinobu and Kawato 1960, 215]

ae.ro.co.lo.ni′ge.nes. Gr. n. *aer* air; L. n. *colonia* a colony; N.L. suff. *-genes* (from Gr. v. *gennaô* to produce) producing; N.L. fem. adj. *aerocolonigenes* producing aerial colonies.

Branching substrate mycelium is produced (diameter approx. 0.5 µm); on some media extremely sparse aerial hyphae are formed. Some strains may appear to form clumps of interwoven hyphae or "colonies" in the aerial mycelium. Substrate and aerial mycelium fragment. Strains usually lose their capacity to form aerial mycelium during subcultivation.

Yellowish to brownish substrate mycelium is produced along with extremely sparse white aerial hyphae. Yellowish to brownish soluble pigment is produced on several media. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 70–71 (T_m).

Type strain: NRRL B-3298, ATCC 23870, CCRC 13661, DSM 40034, IFO 13195, JCM 4150.

Sequence accession no. (16S rRNA gene): AF114804.

2. **Lechevalieria flava** (Gauze, Maksimova, Ollkhovatova, Sveshnikova, Kochetkova and Ilchenko 1974) Labeda, Hatano, Kroppenstedt and Tamura 2001, 1050[VP] [*Saccharothrix flava* (Gauze, Maksimova, Ollkhovatova, Sveshnikova, Kochetkova and Ilchenko 1974) Grund and Kroppenstedt 1990a, 320 (Effective publication: Grund and Kroppenstedt 1989, 271.); *Nocardiopsis flava* (Gauze, Maksimova, Ollkhovatova, Sveshnikova, Kochetkova and Ilchenko 1974) Gauze and Sveshnikova 1985, 224; (Effective publication: Preobrazhenskaya, Sveshnikova and Gauze 1982, 111.); *Actinomadura flava* Gauze, Maksimova, Ollkhovatova, Sveshnikova, Kochetkova and Ilchenko 1974[AL]]

fla′va. L. fem adj. *flava* yellow (referring to the color of the substrate mycelium).

Substrate mycelium is usually yellowish in color and aerial mycelium, if present, is white. Special spore forming hyphae are absent. Long, straight aerial mycelium fragments completely into spores. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: NRRL B-16131, ATCC 29533, CCRC 13328, DSM 43885, NBRC 14521, INA 2171, JCM 3296.

Sequence accession no. (16S rRNA gene): AF114808.

3. **Lechevalieria fradiae** Zhang, Xie, Liu and Goodfellow 2007a, 834[VP]

fra′di.ae. N.L. gen. n. *fradiae* of Fradia, a patronymic.

Substrate mycelium is yellow to orange in color. Aerial mycelium is not produced. Substrate mycelium fragments into coccoid to coccoidal–rod-shaped elements. No soluble pigments are produced. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 68.0 (T_m).

Type strain: Z6, CGMCC 4.3506, JCM 14205, NRRL B-24612.

Sequence accession no. (16S rRNA gene): AY114175.

4. **Lechevalieria xinjiangensis** Wang, Zhang, Tang, Mao, Wei, Huang, Liu, Shi and Goodfellow 2007, 2821[VP]

xin.ji.ang.en′sis. N.L. fem. adj. *xinjiangensis* referring to Xinjiang, north-western China, the source of the isolate.

Substrate mycelium is yellow to orange in color. Moderate amounts of white to yellow aerial mycelium produced on Bennett's or Gauze No. 1 agar, whereas brownish aerial mycelium is formed on other media. Substrate mycelium fragments into coccoid to coccoidal–rod-shaped elements. No soluble pigments are produced. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 68.6 (T_m).

Type strain: R24, CGMCC 4.3525, DSM 45081, NRRL B-24613.

Sequence accession no. (16S rRNA gene): DQ898283.

Genus XI. **Lentzea** Yassin, Rainey, Brzezinka, Jahnke, Weissbrodt, Budzikiewicz, Stackebrandt and Schaal 1995, 362[VP] emend. Labeda, Hatano, Kroppenstedt and Tamura 2001, 1049

David P. Labeda

Lent′ze.a. N.L. fem. n. *Lentzea* named after Friedrich A. Lentze, a German microbiologist who devoted a considerable part of his life to studying pathogenic actinomycetes.

Branched vegetative mycelia (diameter approx. 0.5 to 0.7 µm); aerial mycelium is produced and fragments into rod-shaped elements. Gram-stain-positive. Resistant to lysozyme. Catalase-positive. Aerobic. **The cell wall contains *meso*-diaminopimelic acid as the diamino acid. The characteristic whole-cell sugars are galactose, mannose, and ribose. The phospholipid pattern consists of significant amounts of phosphatidylethanolamine along with diphosphatidylglycerol, phophatidylglycerol, and phosphatidylinositol. The principal menaquinone is MK-9(H_4).** The fatty acid profile consists of straight-chain saturated, unsaturated, and branched-chain saturated fatty acids of the iso and anteiso types, in addition to tuberculostearic acid. **Phylogenetically, the genus *Lentzea* represents a line of descent adjacent to the genus *Actinosynnema* and close**

to the genera *Lechevalieria*, *Saccharothrix*, and *Umezawaea*. The 16S rRNA gene sequence contains genus-specific diagnostic nucleotide signature patterns of TCAA (617–620) and GCC (843–845).

DNA G+C content (mol%): 68.6–79.6 (HPLC, T_m)

Type species: **Lentzea albidocapillata** Yassin, Rainey, Brzezinka, Jahnke, Weissbrodt, Budzikiewicz, Stackebrandt and Schaal 1995, 362[VP].

Further descriptive information

The genus *Lentzea* was proposed by Yassin et al. (1995) for a single strain, which was isolated from a tissue sample taken from an abdominal mass of a patient with peritoneal carcinomatosis, on the basis of 16S rRNA gene phylogeny, and chemotaxonomic properties that distinguished it from the closely related genus *Saccharothrix*. Lee et al. (2000b) subsequently proposed, based on their chemotaxonomic and phylogenetic studies, that the genus *Lentzea* should be considered a later synonym of *Saccharothrix*. A subsequent study by Labeda et al. (2001), however, demonstrated that *Lentzea* was indeed a valid genus and could be differentiated from the genera *Saccharothrix* and *Lechevalieria* on the basis of phylogenetic position (see Figure 290 in the treatment of the genus *Lechevalieria*), diagnostic signature nucleotides TCAA (617–620) and GCC (843–845) in 16S rRNA gene sequences, and the presence of distinct chemotaxonomic characteristics. *Lentzea* species lack phosphatidylethanolamine containing 2-hydroxy-fatty acids in their polar lipid profiles, differentiating them from members of the genus *Saccharothrix*, and their whole-cell sugar pattern, consisting of galactose, mannose, and small quantities of ribose, differentiates them from both *Lechevalieria* and *Saccharothrix*.

Enrichment and isolation procedures

The first human clinical isolate of *Lentzea albidocapillata* was from a tissue sample; it was isolated from a streak culture on a Columbia blood agar plate. Subsequently, described species have generally been isolated from soil samples from China, Korea, and the United States, indicating that they most likely have a global distribution. Most recently, *Lentzea kentuckyensis* was isolated from an equine placenta, although this species is probably not pathogenic. Media typically used to isolate actinomycetes from environmental samples (i.e. soil and water samples), such as tap water agar or starch-casein agar (Küster and Williams, 1964) supplemented with antifungal antibiotics (cycloheximide, 50 µg/ml), can be used to obtain novel isolates of the genus *Lentzea*.

Maintenance procedures

Working cultures of *Lentzea* can be maintained as refrigerated (4°C) agar slants on an appropriate medium such as yeast extract-malt extract medium (Shirling and Gottlieb, 1966) or NZamine medium (DSMZ medium 554; DSMZ, 2001). The slants are generally incubated for 5 to 7 d at 28–30°C prior to refrigeration and then should be subcultured at monthly intervals. Longer term preservation of strains is best accomplished as frozen stocks in 20% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques. Strains have also been successfully stored for shorter periods as quick-frozen stationary-phase broth cultures or mycelial suspensions in 20% aqueous glycerol at −20 to −72°C.

Procedures for testing special characters

Strains are routinely cultivated on NZamine medium (DSMZ medium 554) at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and NZamine medium.

Chemotaxonomic analysis of strains for cell-wall diamino acid isomer and diagnostic whole-cell sugar content are determined by the methods of Staneck and Roberts (1974) and Saddler et al. (1991). Determination of cellular fatty acids, menaquinones, and polar lipids are performed using methods described previously by Grund and Kroppenstedt (1989), Minnikin et al. (1984), and Sasser (1990).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, guanine, hippurate, hypoxanthine, tyrosine, urea, and xanthine, are typically evaluated using the media of Gordon et al. (1974). Phosphatase activity is evaluated by using the method of Kurup and Schmitt (1973) substituting NZamine agar as the basal medium. The temperature range for growth is determined on slants of DSMZ medium 554 and salt tolerance is determined on slants of the same medium supplemented with 4% and 5% NaCl.

Differentiation of the genus *Lentzea* from other genera

Morphologically, *Lentzea* species are quite similar to species within the genera *Lechevalieria* and *Saccharothrix* producing aerial mycelium which may exhibit a "zig-zag" morphology (Figure 310a) and fragments into coccoidal-rod-shaped elements (Figure 310b). The chemotaxonomic characteristics of members of this genus (see Table 248 in the treatment of the genus *Lechevalieria*) include a polar lipid profile which lacks 2-hydroxy-fatty acid containing phosphatidylethanolamine and contains phosphatidylinositol and phosphatidylglycerol, differentiating them from *Saccharothrix* species. The sugars observed in their whole-cell sugar profiles include galactose, mannose, and small quantities of ribose, but no rhamnose, which differentiates them from both *Lechevalieria* and *Saccharothrix* species. The genus *Lentzea* can also be differentiated from the genera *Lechevalieria* and *Saccharothrix* phylogenetically and based on the genus-specific nucleotide signature patterns TCAA (617–620) and GCC (843–845) in their 16S rRNA gene sequence (see Figure 290 and Figure 309).

Differentiation of the species of the genus *Lentzea*

The physiological characteristics of *Lentzea* species are summarized in Table 251 and can be used to differentiate between species, although a common set of physiological tests has not been used in the description of all species. Gross colonial morphology provides some additional information of the species based on color of the substrate mycelium, production and color of aerial mycelium, and production and color of soluble pigments when grown on agar media. The distinct fatty acid profiles of each *Lentzea* species, as shown in Table 252, can also be used to differentiate between species.

List of species of the genus *Lentzea*

1. **Lentzea albidocapillata** Yassin, Rainey, Brzezinka, Jahnke, Weissbrodt, Budzikiewicz, Stackebrandt and Schaal 1995, 362[VP]

al.bi.do.ca.pil.la′ta. L. adj. *albidus* white; L. adj. *capillatus* hairy; N.L. fem. adj. *albidocapillata* white haired, referring to the abundant whitish aerial hyphae.

Substrate mycelium is yellow to yellowish-brown. Aerial mycelium is white to whitish-yellow. Soluble pigments are not produced. Temperature for growth is 30°C.

Source: isolated originally from the peritoneal cavity of a cancer patient.

DNA G+C content (mol%): 68.6 (HPLC).

Type strain: DSM 44073, AS 4.1519, CIP 107111, NBRC 15855, JCM 9732, NBRC 100372.

Sequence accession no. (16S rRNA gene): X84321.

Further comment: Lee et al. (2000b) suggested that *Lentzea albidocapillata* be transferred to the genus *Saccharothrix* Labeda et al. 1989, but phylogenetic and chemotaxonomic data do not support this proposal according to Labeda et al. (2001). *Lentzea* is considered to be the current correct name of a genus in which the type strain is *Lentzea albidocapillata*.

2. **Lentzea albida** Labeda, Hatano, Kroppenstedt and Tamura 2001, 1049[VP]

al.bi′da. L. fem. adj. *albida* whitish, referring to the color of the aerial mycelium.

Substrate mycelium is yellowish-orange in color on most media. Copious white aerial mycelium is produced. Soluble pigments are not produced. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: NBRC 16102, AS 4.1727, DSM 44437, JCM 9734, KCTC 19911, NRRL B-24073.

Sequence accession no. (16S rRNA gene): AB006167.

3. **Lentzea californiensis** Labeda, Hatano, Kroppenstedt and Tamura 2001, 1049[VP]

cal.i.forn.i.en′sis. N.L. fem. adj. *californiensis* pertaining to California, referring to the source of this isolate, soil from California.

Substrate mycelium is yellow to orange-brown. White aerial mycelium is produced. An orange soluble pigment may be produced on Czapek's agar. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: NRRL B-16137, DSM 43393, IMRU 550, JCM 11305, KCTC 19912.

Sequence accession no. (16S rRNA gene): AF174435.

4. **Lentzea flaviverrucosa** Xie, Wang, Huang, Wu, Ba and Liu 2002, 1818[VP]

fla.vi.ver.ru.co′sa. L. adj. *flavus* yellow; L. adj. *verrucosus* rough, rugged, verrucose; N.L. fem. adj. *flaviverrucosa* yellowish and verrucose, referring to the yellowish, verrucose colony morphology observed on the agar surface.

Substrate mycelium is pale yellow to yellowish-brown on most media. Sparse white to yellowish-white aerial mycelium is produced on some media (e.g. oatmeal agar). Neither melanin nor soluble pigments are produced. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 64.1 (T_m).

Type strain: AS 4.0578, CIP 107743, DSM 44664, JCM 11373, NBRC 100042.

Sequence accession no. (16S rRNA gene): AF183957.

5. **Lentzea kentuckyensis** Labeda, Donahue, Sells and Kroppenstedt 2007, 1782[VP]

ken.tuck.y.en′sis. N.L. fem. adj. *kentuckyensis* from Kentucky, named after the place of origin of the type strain, the state of Kentucky, USA.

Yellow to strong yellow substrate mycelium is produced on most media. Aerial mycelium ranging in color from white to yellowish-white is produced on most media. A faint brown soluble pigment is produced on some media. Temperature for growth is 28°C.

Source: isolated from an equine placenta.

DNA G+C content (mol%): not determined.

Type strain: NRRL B-24416, LDDC 2876-05, DSM 44909.

Sequence accession no. (16S rRNA gene): DQ291145.

6. **Lentzea violacea** (Lee, Kim, Roe, Kim, Kang and Hah 2000b) Labeda, Hatano, Kroppenstedt and Tamura 2001, 1049[VP] (*Saccharothrix violacea* Lee, Kim, Roe, Kim, Kang and Hah 2000b, 1320)

vi.o.la.ce′a. L. fem. adj. *violacea* violet-colored, violet.

Violet substrate mycelium and a white aerial mycelium produced on most media. Reddish-brown soluble pigment is produced. Melanin pigment is not produced. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 79.6 (HPLC).

Type strain: IMSNU 50388, DSM 44796, JCM 10975, KCTC 9948.

Sequence accession no. (16S rRNA gene): AJ242633.

7. **Lentzea waywayandensis** (Labeda and Lyons 1989) Labeda, Hatano, Kroppenstedt and Tamura 2001, 1049[VP] (*Saccharothrix waywayandensis* Labeda and Lyons 1989, 357)

way.way.an.den′sis. N.L. fem. adj. *waywayandensis* of or belonging to Lake Waywayanda, NJ, of the soil samples from which the organism was first isolated.

Substrate mycelium is pale yellow to dark yellow. Aerial mycelium is white when produced, particularly on inorganic salts-starch agar (ISP medium 4). Soluble pigments are not produced. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 71 (T_m).

Type strain: NRRL B-16159, AS 4.1646, ATCC 51594, DSM 44232, NBRC 14970, JCM 9114, NCIMB 13164, VKM Ac-1970.

Sequence accession no. (16S rRNA gene): AF114813.

Genus XII. **Prauserella** Kim and Goodfellow 1999, 510^{VP} emend. Li, Xu, Tang, Xu, Kroppenstedt, Stackebrandt and Jiang 2003c, 1547

Seung Bum Kim and Michael Goodfellow

Prau.se.rel′la. N.L. fem. dim. n. *Prauserella* named after Helmut Prauser, a German microbiologist who made many contributions to actinomycete systematics.

Aerobic, Gram-stain-positive, non-acid–alcohol-fast, nonmotile actinobacteria which form an extensively branched substrate mycelium (0.6–0.8 µm in diameter) that **fragments into irregular rod-shaped elements within 24–48 h on rich media**. Aerial hyphae, when formed, may differentiate into branched short or, at maturity, long chains which have a straight to flexuous arrangement. Spores are nonmotile. **Most strains grow optimally in the presence of 10% or between 10 and 15% NaCl at 28°C and pH 7.0.** Optimal growth occurs between pH 6.8 and 7.2. The temperature range for growth is 10–45°C, with optimal growth between 28 and 34°C. **Contains *meso*-diaminopimelic acid as the major diamino acid, an acetylated peptidoglycan, major amounts of arabinose and galactose, MK-9(H_4) as the predominant menaquinone, either phosphatidylcholine or phosphatidylethanolamine as the diagnostic phospholipid, and major amounts of branched chains and saturated fatty acids, but not mycolic acids.**

The genus *Prauserella*, as determined by 16S rRNA gene sequence analysis, is classified in the family *Pseudonocardiaceae.*

DNA G+C content (mol%): 65.8–70.1.

Type species: **Prauserella rugosa** (Lechevalier, Prauser, Labeda and Ruan 1986) Kim and Goodfellow 1999, 510^{VP}.

Further descriptive information

Phylogeny. The genus *Prauserella* forms a distinct branch within the evolutionary radiation occupied by the family *Pseudonocardiaceae* and is most closely related to the genus *Saccharomonospora* (Labeda et al., 2010a). The nine species assigned to the genus (Figure 311) share 16S rRNA gene sequence similarities which range from 95.8% between *Prauserella halophila* and *Prauserella muralis* to 100% between *Prauserella flava* and *Prauserella salsuginis.* The level of DNA–DNA relatedness between the latter two species is 56.9% (Li et al., 2009b).

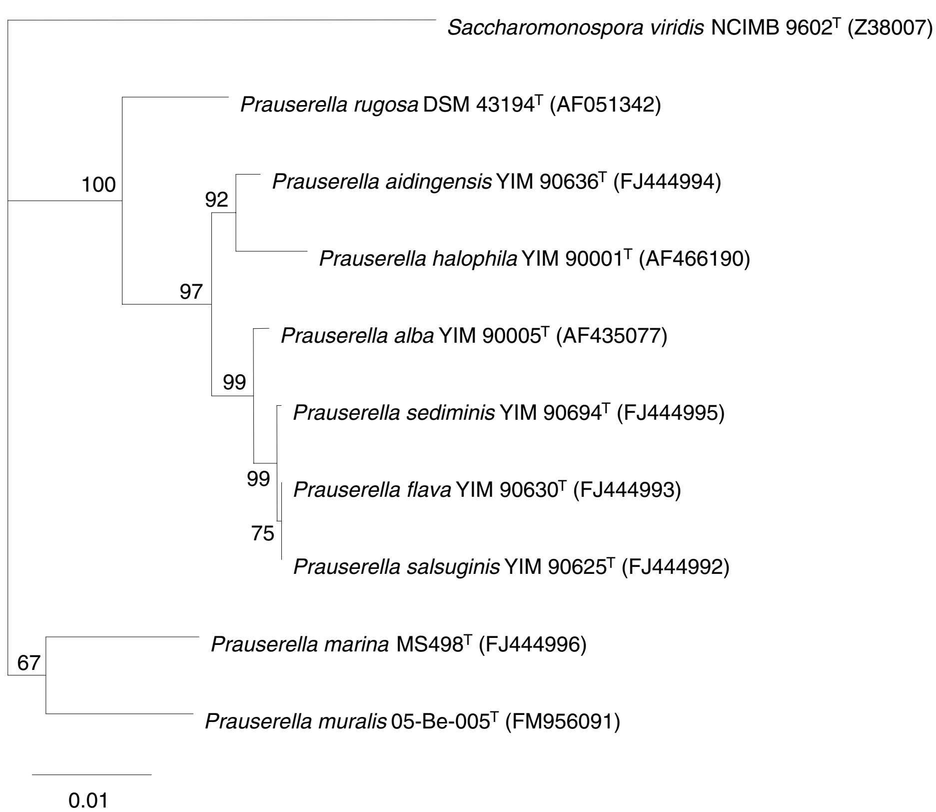

FIGURE 311. Neighbor-joining tree (Saitou and Nei, 1987) based on nearly complete 16S rRNA gene sequences showing the relationships between *Prauserella* species and representatives of some other genera classified in the family *Pseudonocardiaceae.* Numbers at the nodes indicate levels of bootstrap support (Felsenstein, 1985) based on analysis of 1000 datasets. Bar = 0.01 substitutions per nucleotide position.

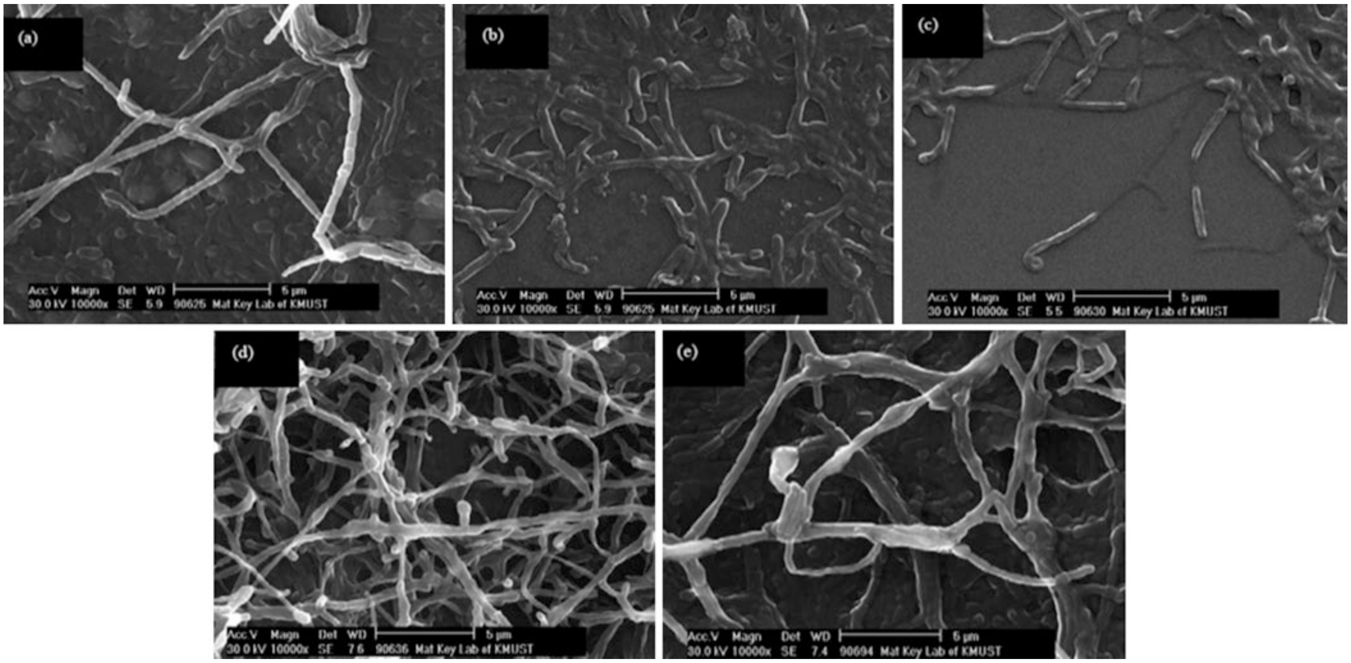

FIGURE 312. Scanning electron micrographs showing the morphology of *Prauserella aidingensis* YIM 90636^T, *Prauserella flava* YIM 90630^T, *Prauserella salsuginis* YIM 90625^T, and *Prauserella sediminis* YIM 90694^T grown on yeast extract-malt extract agar (ISP medium 2; Shirling and Gottlieb, 1966) at 28°C for 23 d (bars = 5 µm). (a) Spore chains of strain YIM 90625^T; (b) substrate mycelium of strain YIM 90625^T; (c) substrate mycelium of strain YIM 90630^T; (d) spore chains of strain YIM 90636^T; and (e) spore chains of strain YIM 90694^T. (Reproduced with permission from Li et al., 2009b. Int. J. Syst. Evol. Microbiol. *59*: 2928–2932.)

Cell morphology. *Prauserella* strains form a substrate mycelium which usually carries aerial hyphae, although *Prauserella flava* and *Prauserella rugosa* do not form an aerial mycelium (Lechevalier et al., 1986; Li et al., 2009b). Substrate mycelia fragment into rod-shaped elements and aerial hyphae may differentiate into branched short or, at maturity, long chains, which are straight to flexuous (Figure 312).

Chemotaxonomy. *Prauserella* strains contain *meso*-diaminopimelic acid as the diagnostic wall diamino acid and arabinose and galactose as major whole-cell sugars (Lechevalier et al., 1986; Li et al., 2009b; Mertz and Yao, 1993), i.e. they have wall chemotype IV *sensu* Lechevalier and Lechevalier (1970). Other major sugars may be detected in whole-cell hydrolysates, notably ribose (Table 253). In addition, all *Prauserella* strains have tetrahydrogenated menaquinones, MK-9(H_4), as the predominant isoprenologue, although *Prauserella rugosa* also contains a large amount of MK-9(H_2); small amounts of other menaquinones (<7%) may be detected (Lechevalier et al., 1986; Li et al., 2009b; Schäfer et al., 2010). *Prauserella rugosa* has *N*-acetylated muramic acid (Henssen et al., 1987).

Prauserellae can be assigned to two groups based on the discontinuous distribution of diagnostic polar lipids, although they all have patterns which include diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, phosphatidylethanolamine, and, in some instances, unknown phospholipids (Li et al., 2009b; Schäfer et al., 2010; Wang et al., 2010). *Prauserella alba*, *Prauserella halophila*, *Prauserella muralis*, and *Prauserella rugosa* contain phosphatidylethanolamine as the diagnostic polar lipid, whereas phosphatidylcholine is the diagnostic marker in *Prauserella aidingensis*, *Prauserella flava*, *Prauserella marina*, *Prauserella sediminis*, and *Prauserella salsuginis*; hence, these two groups have phospholipid patterns II and III, respectively (Lechevalier et al., 1977b, 1981). Hydroxyphosphatidylethanolamine and hydroxymethylphosphatidylethanolamine have been detected in *Prauserella rugosa* (Lechevalier et al., 1986; Yassin et al., 1993) and phosphatidylserine has been found in *Prauserella muralis* (Schäfer et al., 2010).

Prauserella strains contain complex mixtures of branched-chain and saturated fatty acids (Henssen et al., 1987; Li et al., 2003c; Mertz and Yao, 1993), but lack mycolic acids (Henssen et al., 1987; Lechevalier et al., 1986). The principal fatty acid, 14-methylpentadecanoic acid ($C_{16:0}$ iso), accounts for between 20 and 42% of total fatty acid composition; other major components (<10%) may include $C_{16:0}$, $C_{17:1}$ anteiso, and $C_{16:1}$ ω9*c* (Li et al., 2009b; Schäfer et al., 2010; Wang et al., 2010).

Nutritional and growth conditions. Prauserellae tend to grow well on standard media used to cultivate filamentous actinobacteria, such as Czapek's agar, glycerol-asparagine agar (ISP medium 5), inorganic salts-starch agar (ISP medium 4), nutrient agar, oatmeal agar (ISP medium 3) and yeast extract-malt extract agar (ISP medium 2) supplemented with 10% (w/v) NaCl and incubated at 28–37°C; the composition of the ISP media is given by Shirling and Gottlieb (1966). Most strains are either halophilic or halotolerant. However, *Prauserella marina* grows optimally on yeast extract-malt extract agar without NaCl at 28–37°C and pH 7.0 (Wang et al., 2010).

Metabolism and ecology. Little is known about the biological properties of *Prauserella* strains or of their distribution and activities in natural habitats. They are aerobic, have an oxida-

[a]Symbols: +, positive; –, negative; nd, not determined.

[b]Data from Kim and Goodfellow (1999), Li et al. (2003c, 2009b), Schäfer et al. (2010), and Wang et al. (2010).

[c]In addition, all species contain arabinose and galactose.

[d]PC, Phosphatidylcholine; PE, phosphatidylethanolamine; PS, phosphatidylserine.

tive metabolism, grow on a broad range of sole carbon and sole nitrogen compounds, and tend to grow optimally in the presence of 8–15% (w/v) NaCl (Li et al., 2003c, 2009b; Schäfer et al., 2010; Wang et al., 2010). The type strain of *Prauserella rugosa* hydrolyzes arbutin, allantoin, and esculin, degrades several organic compounds, and is active against a broad range of 4-methylumbelliferone and 7-amino-4-methylcoumarin-conjugated fluorogenic compounds (De Boer et al., 1990); it also produces alkaline hydrolases when grown on *n*-dodecane (Smits et al., 1999). Most *Prauserella* strains have been isolated from saline habitats (Li et al., 2003c, 2009b; Wang et al., 2010), although *Prauserella muralis* was obtained from a wall colonized by fungi (Schäfer et al., 2010) and *Prauserella rugosa* was from the rumen of a cow (di Marco and Spalla, 1957).

Isolation procedures

Prauserella species have been isolated by plating serial dilutions of saline samples onto starch-casein agar supplemented with 20% (w/v) NaCl and incubating for about 4 weeks at 28°C (Li et al., 2003c) and by plating onto cellulose-casein multi-salt medium and incubating for 3 weeks at 37°C (Li et al., 2009b; Tang et al., 2008). *Prauserella marina* was obtained from a marine sediment sample following incubation at 22°C for 4 weeks on MOPS-proline agar (Wang et al., 2010) and *Prauserella muralis* was isolated by shaking a 1 g sample of plaster colonized by molds in 10 ml NaCl (0.9%, w/v) containing Tween 80 (0.01%, v/v) then plating aliquots of the suspension over starch-mineral agar plates (Gauze, 1985), which were then incubated for 2 weeks at 28°C (Schäfer et al., 2010).

Maintenance procedures

Working cultures of *Prauserella* can be maintained at 4°C on standard media such as modified Bennett's (Jones, 1949), organic medium M79 (Schäfer et al., 2010), and yeast extract-malt extract (Shirling and Gottlieb, 1966) agars supplemented with 10% (w/v) NaCl for halophilic and halotolerant strains. Moderate to long-term preservation can be achieved by storing mycelial spore suspensions in aqueous glycerol (10 or 20%, v/v) at −20 or −80°C (mechanical freezers), at −172°C (liquid nitrogen vapor phase), or by standard lyophilization techniques.

Procedures for testing special characters

Reliable and well established procedures are available for analysis of the isomers of diaminopimelic acid and whole-cell sugars (Hasegawa et al., 1983a; Staneck and Roberts, 1974), fatty acids (Sasser, 1990), and menaquinones and polar lipids (Minnikin et al., 1984). Physiological features, such as the production of acids from sugars, growth on sole carbon and nitrogen compounds, and degradation of complex organic substrates, can be determined using standard methods (De Boer et al., 1990; Shirling and Gottlieb, 1966; Williams et al., 1983).

Differentiation of the genus *Prauserella* from other genera

Prauserella strains can be distinguished from other actinobacteria classified in the family *Pseudonocardiaceae* by using a combination of chemotaxonomic and morphological features and by comparative 16S rRNA gene sequence analyses (Kim and Goodfellow, 1999; Labeda et al., 2010a), as shown in the treatment of the family *Pseudonocardiaceae* in this volume. The genus can be separated from other filamentous actinobacteria using genus-specific 16S rRNA gene restriction fragment patterns (Cook and Meyers, 2003).

Taxonomic comments

The monospecific genus *Prauserella*, with *Prauserella rugosa* as the type species, was proposed by Kim and Goodfellow (1999) for an organism which had been isolated from the rumen of a cow and designated "*Nocardia rugosa*" (di Marco and Spalla, 1957). The taxon was well described, although a type species was not designated until the species was transferred to the genus *Amycolatopsis* as *Amycolatopsis rugosa*, a move based on chemotaxonomic and morphological criteria (Lechevalier et al., 1986). This transfer proved to be a temporary one as the organism was shown to differ from *bona fide* members of the genus *Amycolatopsis* based on fatty acid (Henssen et al., 1987; Mertz and Yao, 1993), DNA–DNA relatedness (Labeda, 1995), and extensive phenotypic (De Boer et al., 1990) data. In addition, the organism did not give the characteristic amplification product with *Amycolatopsis* genus-specific primers (Tan et al., 2006b) and formed a distinct single-membered cluster in a numerical taxonomic study which included strains that were subsequently classified in the genus *Amycolatopsis* (Goodfellow, 1971). The genus *Prauserella* currently contains nine species, most of which were circumscribed in polyphasic studies which included DNA–DNA relatedness data (Li et al., 2003c, 2009b). The original description of the genus was emended by Li et al. (2003c).

Differentiation of the species of the genus *Prauserella*

Prauserella species can be distinguished using a combination of phenotypic properties (Table 253) and by DNA–DNA relatedness data (Li et al., 2003c, 2009b). Qualitative and quantitative differences have been found in the fatty acid profiles of some species (Li et al., 2009b; Schäfer et al., 2010; Wang et al., 2010).

List of species of the genus *Prauserella*

1. **Prauserella rugosa** (Lechevalier, Prauser, Labeda and Ruan 1986) Kim and Goodfellow 1999, 510[VP] (Basonym: *Amycolatopsis rugosa* Lechevalier, Prauser, Labeda and Ruan 1986, 35 *ex* di Marco and Spalla 1957; "*Nocardia rugosa*" di Marco and Spalla 1957, 28.)

ru.go′sa. L. fem. adj. *rugosa* wrinkled.

Forms an extensively branched substrate mycelium that fragments into irregular rods. Aerial hyphae are not formed. Cream colored, irregular, flat, and veined colonies (10 × 6 mm) are formed on Czapek Dox-yeast extract agar. Good growth occurs on Bennett's, modified Bennett's, and nutrient agars. Produces cream to yellowish glistening colonies which may be wrinkled or folded. Brownish soluble pigments are formed on some media. The temperature range for growth is 10–45°C, with an optimum at 34°C. Grows optimally between pH 6.8 and 7.2.

Allantoin and esculin are hydrolyzed. Produces phosphatase, but does not reduce nitrate or produce hydrogen sulfide. Acetate, benzoate, lactate, malate, propionate, pyruvate, and succinate are decarboxylated, but not citrate, mucate, oxalate, or tartrate. 2-Deoxythymidine-5-*para*-nitrophenyl (*p*NP) phosphate, *p*NP-α-D-glucopyranoside, and *p*NP-β-D-glucopyranoside are hydrolyzed, but not L-alanine-D-nitroanilide (*p*NA), *bis*-*p*NP phosphate, *o*NP-β-D-galactopyranoside, *p*NP-glucopyranoside, *p*NP-β-D-glucuronide, L-glutamate-γ-3-carbonyl-*p*NP, *p*NP-phenylphosphonate, *p*NP-phosphorylcholine, L-proline-*p*NA, or *p*NP-β-D-xylopyranoside.

Arbutin, casein, hypoxanthine, L-tyrosine, tributyrin, Tweens 20, 40, 60 and 80, and xanthine are degraded, but not adenine, elastin, starch, or testosterone.

Acid is formed from adonitol, L-arabinose, erythritol, fructose, galactose, glucose, glycerol, mannitol, mannose, rhamnose, salicin, trehalose, and xylose, but not from D-arabinose, cellobiose, dextrin, inositol, lactose, maltose, melibiose, methyl α-D-glucoside, raffinose, sorbitol, sucrose, or methyl β-D-xyloside.

Adonitol, amygdalin, arbutin, dextrin, erythritol, glycerol, glycogen, salicin, and sucrose are used as sole carbon sources for energy and growth, but not arabitol, dulcitol, D- or L-fucose, gentiobiose, glucose, sorbitol, or turanose (at 1%, w/v). L-Alanine, androsterone, cholesterol, ergosterol, L-glycine, L-proline, protocatechuic acid, shikimic acid, butyrate, propionate, pyruvate, succinate, and L-tyrosine are also used as sole carbon sources, but not α-D-alanine, L-arginine, L-asparagine, catechol, L-citrulline, creatine, L-cysteine, ferulic acid, gluconate, glucuronate, histamine, L-hydroxyproline, phthallic acid, progesterone, quinic acid, L-serine, fumarate, tartrate, syringealdehyde, L-threonine, or vanillin (all at 0.1%, w/v). Does not use L-histidine, L-ornithine, or L-phenylalanine as sole nitrogen sources.

Grows in the presence of (μg/ml) cephaloridine (2), demeclocycline (2), lincomycin (10), neomycin (3), oleandomycin (2), penicillin G (10), streptomycin (16), and vancomycin (0.25), but is sensitive to cephaloridine (25), chloramphenicol (25), gentamicin (0.5), kanamycin (5),

rifampin (2), tetracycline (5), and tobramycin (8). Similarly, growth occurs in the presence of (μg/ml) bismuth citrate (1), crystal violet (1), phenol (100), phenyl ethanol (0.1%, v/v), potassium tellurite (10), sodium azide (1), teepol (100), tetrazolium (100), thallous acetate (10), and sodium chloride (13%, w/v), but is sensitive to adenine (0.4%, w/v), crystal violet (10), phenyl ethanol (0.4%, v/v), potassium tellurite (100), sodium azide (100), and thallous acetate (100). Sensitive to lysozyme.

The type strain produces vitamin B_{12}.

Additional phenotypic properties are cited in the text and in Table 253.

Cellular fatty acids consist of major proportions of $C_{16:1}$ iso OH, $C_{16:0}$ iso, and $C_{17:1}$ ω6*c*; smaller proportions (<10%) of $C_{15:0}$ iso, $C_{15:1}$ ω6*c*, $C_{16:1}$ ω7*c* and/or $C_{15:0}$ iso 2-OH, $C_{15:0}$, $C_{16:0}$, $C_{16:0}$ 10-methyl, $C_{17:0}$ iso, $C_{17:1}$ ω8*c*, $C_{17:0}$, $C_{18:1}$ iso, and $C_{18:0}$ are found.

Source: isolated from the rumen of a cow.

DNA G+C content (mol%): 67.0–68.9 (T_m).

Type strain: ATCC 43014, CIP 106520, DSM 43194, NBRC 14506, IMRU 3760, JCM 9736, NCIMB 8926, NRRL B-2295, VKM Ac-1243.

Sequence accession no. (16S rRNA gene): AF051342.

2. **Prauserella aidingensis** Li, Tang, Chen, Wu, Zhi, Zhang and Li 2009b, 2926[VP]

ai.ding.en′sis. N.L. fem. adj. *aidingensis* of or belonging to Aiding Lake, where the type strain was isolated.

Forms a substrate mycelium that fragments and which carries a white aerial mycelium. Colonies are light gray-white on glycerol-asparagine agar (ISP medium 5), slightly gray-white on oatmeal agar (ISP medium 3), and brilliant yellow on potato and yeast extract-malt extract (ISP medium 2) agars. Grows at 15–45°C, pH 6.0–9.0, and 5–15% (w/v) NaCl on ISP 2 medium; optimal conditions are 28–37°C, pH 7, and 8–10% NaCl. Catalase-positive, but oxidase-negative. Coagulates milk, but is negative for H_2S production. L-Alanine, L-histidine, L-hydroxyproline, L-phenylalanine, L-proline, DL-tryptophan, L-tyrosine, L-xanthine, and L-valine are used as sole nitrogen sources, but not adenine or DL-methionine.

The DNA–DNA relatedness value between the type strain and that of *Prauserella sediminis* is 47.9%.

Additional phenotypic properties are cited in the text and in Table 253.

Cellular fatty acids contain major proportions of $C_{16:0}$ iso and $C_{16:1}$ ω9*c*; smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{15:0}$ iso, $C_{15:1}$ B, $C_{16:0}$, $C_{16:0}$ iso 2-OH, $C_{16:1}$ iso H, $C_{17:0}$, $C_{17:0}$ iso 2-OH, $C_{17:0}$ anteiso, $C_{17:1}$ anteiso, and $C_{18:1}$ 2-OH, and traces of $C_{17:0}$ anteiso 2-OH are found.

Source: isolated from a salt lake.

DNA G+C content (mol%): 70.1 (HPLC).

Type strain: CCTCC AA 208053, DSM 45266, YIM 90636.

Sequence accession no. (16S rRNA gene): FJ444994.

3. **Prauserella alba** Li, Xu, Tang, Xu, Kroppenstedt, Stackebrandt and Jiang 2003c, 1548[VP]

al′ba. L. fem. adj. *alba* white, referring to the white aerial mycelium.

Forms a branched substrate mycelium which undergoes fragmentation. Substrate mycelia may be light orange-yellow (Czapek's and nutrient agars), gray-white (oatmeal agar; ISP medium 3), orange-yellow (yeast extract-malt extract agar; ISP medium 2), and ranges from yellow-white to light yellow on glucose-asparagine agar (ISP medium 5), inorganic salts-starch agar (ISP medium 4), and nutrient agar; all of these media were supplemented with 10% (w/v) NaCl. Diffusible pigments are not formed. White aerial hyphae differentiate into branched short or, at maturity, long, straight to flexuous spore chains on Czapek's agar. Optimal growth occurs on Czapek's agar supplemented with 10% (w/v) NaCl at 28°C and pH 7.0.

Does not hydrolyze esculin. *p*NP-α-D-Glucopyranoside is hydrolyzed, but not L-alanine-*p*NA, *bis*-*p*NP phosphate, 2-deoxythymidine-5-*p*NP phosphate, *o*NP-β-D-galactopyranoside, *p*NP-glucopyranoside, *p*NP-β-D-glucuronide, L-glutamate-γ-carbonyl-*p*NP, *p*NP-phenylphosphonate, *p*NP-phosphorylcholine, L-proline-*p*NA, or *p*NP-β-D-xylopyranoside. Utilizes acetate, *N*-acetyl-D-glucosamine, *cis*- and *trans*-aconitate, adipate, L-alanine, L-arabinose, citrate, L-histidine, 3-hydroxy-DL-butyrate, DL-lactate, L-leucine, L-malate, maltose, D-mannose, oxoglutarate, phenylacetate, L-phenylalanine, L-proline, pyruvate, L-serine, D-sorbitol, suberate, and trehalose, but not 4-aminobutyrate, L-aspartate, azelate, glutarate, itaconate, 4-hydroxybenzoate, or L-ornithine. DNA–DNA relatedness values between the type strain and those of other *Prauserella* species are as follows: *Prauserella aidingensis*, 41.4%; *Prauserella flava*, 43.6%; *Prauserella salsuginis*, 47.2%; and *Prauserella sediminis*, 51.6%.

Additional phenotypic features are cited in the text and in Table 253.

Cellular fatty acids contain major proportions of $C_{16:0}$ and $C_{16:0}$ 2-OH; smaller proportions (<10%) of $C_{14:0}$ iso, $C_{15:0}$ iso, $C_{15:1}$ B, $C_{16:0}$, $C_{16:1}$ *cis*9, $C_{16:1}$ iso H, $C_{17:0}$ iso, $C_{17:0}$ anteiso, $C_{17:0}$ anteiso 2-OH, and $C_{17:1}$ ω9*c*, and traces of $C_{15:0}$, $C_{17:0}$, and $C_{17:0}$ iso 2-OH are found.

Source: isolated from soil in hypersaline habitats.

DNA G+C content (mol%): 66.7 (T_m).

Type strain: CCTCC AA 001016, DSM 44590, YIM 90005.

Sequence accession no. (16S rRNA gene): AF435077.

Additional comments: in the original paper by Li et al. (2003c), strain CCTCC AA 001016 is wrongly cited as CCTCC AA001016.

4. **Prauserella flava** Li, Tang, Chen, Wu, Zhi, Zhang and Li 2009b, 2926[VP]

fla′va. L. fem. adj. *flava* yellow, referring to the color of the substrate mycelium.

Forms a substrate mycelium that undergoes fragmentation. Colonies are light yellow on glycerol-asparagine agar (ISP medium 5), brown on oatmeal agar (ISP medium 3), gray-yellow on potato agar, and brilliant yellow on yeast extract-malt extract agar (ISP medium 2). Does not form aerial hyphae on any of these media. Grows at 15–45°C, pH 6.0–9.0, and 5–15% (w/v) NaCl on ISP medium 2; optimal conditions are 28–37°C, pH 7, and 8–10% NaCl. Catalase-positive, but oxidase-negative. Coagulates milk, but is negative for H_2S production, nitrate reduction, and starch hydrolysis. L-Alanine, L-histidine, L-phenylalanine, L-proline, DL-tryptophan, L-tyrosine, xanthine, and L-valine are used as sole nitrogen sources, but not adenine, L-arginine, or DL-methionine.

DNA–DNA relatedness values of the type strain of *Prauserella flava* with those of *Prauserella aidingensis* and *Prauserella sediminis* are 55.3 and 40.9%, respectively.

Additional phenotypic properties are cited in the text and in Table 253.

Cellular fatty acids consist of major proportions of $C_{16:0}$ iso and $C_{17:1}$ anteiso; smaller proportions (<10%) of $C_{14:0}$, $C_{15:0}$, $C_{15:0}$ iso, $C_{15:1}$ B, $C_{16:0}$, $C_{16:0}$ iso 2-OH, $C_{16:1}$ ω9*c*, $C_{16:1}$ iso H, $C_{17:0}$, $C_{17:0}$ anteiso, and $C_{17:0}$ anteiso 2-OH, and traces of $C_{17:1}$ ω9*c* and $C_{18:1}$ 2-OH are found.

Source: isolated from a salt lake.

DNA G+C content (mol%): 69.9 (HPLC).

Type strain: CCTCC AA 208052, DSM 45265, YIM 90630.

Sequence accession no. (16S rRNA gene): FJ444993.

5. **Prauserella halophila** Li, Xu, Tang, Xu, Kroppenstedt, Stackebrandt and Jiang 2003c, 1548[VP]

ha.lo′phi.la. Gr. n. *hals halos* salt; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *halophila* salt-loving, referring to the ability to grow at high NaCl concentrations.

Forms a branched substrate mycelium which undergoes fragmentation. Substrate mycelium is light orange-brown on Czapek's agar, light gray-white on arginine-glycerol agar (ISP medium 5), light yellow on inorganic salts-starch and yeast extract-malt extract agars (ISP media 4 and 2, respectively), deep gray-white on oatmeal agar (ISP medium 3), and deep yellow on potato agar [all media supplemented with 10% (w/v) NaCl]. Diffusible pigments are not formed. A white to yellow aerial mycelium is well developed on all of these media, apart from ISP medium 2. Aerial hyphae differentiate into branched short or, at maturity, long straight to flexuous spore chains. Optimal growth occurs on Czapek's agar supplemented with 10–15% (w/v) NaCl at 28°C and pH 7.0. Does not hydrolyze esculin, L-alanine-*p*NA, *bis*-*p*NP phosphate, 2-deoxythymidine-5-*p*NP phosphate, *o*NP-β-D-galactopyranoside, *p*NP-α-D-glucopyranoside, *p*NP-glucopyranoside, *p*NP-β-D-glucuronide, L-glutamate-γ-3-cabonyl-*p*NP, *p*NP-phenylphosphonate, *p*NP-phosphorylcholine, L-proline-*p*NP, or *p*NP-β-D-xylopyranoside. Acetate, adipate, L-alanine, azelate, fumarate, L-histidine, 3-hydroxy-DL-butyrate, L-malate, L-phenylalanine, propionate, L-proline, pyruvate, D-sorbitol, and suberate are used as sole carbon sources, but not *N*-acetyl-D-glucosamine, *cis*- or *trans*-aconitate, 4-aminobutyrate, L-arabinose, citrate, glutarate, 4-hydroxybenzoate, itaconate, DL-lactate, L-leucine, maltose, D-mannose, L-ornithine, oxoglutarate, L-phenylacetate, L-serine, or trehalose.

Additional phenotypic properties are cited in the text and in Table 253.

Cellular fatty acids contain major proportions of $C_{16:0}$ iso, $C_{17:1}$ ω6*c*, $C_{16:1}$ ω7*c* and/or $C_{15:0}$ iso 2-OH, and $C_{17:0}$ anteiso, and smaller proportions (<10%) of $C_{14:0}$ iso, $C_{15:0}$ iso, $C_{15:1}$ ω6*c*, $C_{16:1}$ iso H, $C_{16:0}$, $C_{17:0}$ 10-methyl, $C_{17:1}$ ω8*c*, $C_{17:0}$, and $C_{18:1}$ ω9*c*.

DNA–DNA relatedness values between the type strain and those of other *Prauserella* species are as follows: *Prauserella aidingensis*, 53.7%; *Prauserella alba*, 30.2%; *Prauserella flava*, 41.3%; *Prauserella salsuginis*, 20.8%; and *Prauserella sediminis*, 45.2%.

Source: isolated from soil in hypersaline habitats.

DNA G+C content (mol%): 65.8 (T_m).

Type strain: CCTCC AA 001015, DSM 44617, YIM 90001.

Sequence accession no. (16S rRNA gene): AF466190.

Additional comments: the etymology of the first compound of the specific epithet should be Gr. n. *halo halos* salt, not Gr. n. *halo* salt as cited by Li et al. (2003c). Similarly, the specific epithet *halophila* is a "N.L. fem. adj." not a "N.L. gen. adj." as cited by Li and his colleagues who also cited strain CCTCC AA 001015 as CCTCC AA001015.

6. **Prauserella marina** Wang, Li, Bian, Tang, Ren, Chen, Li and Zhang 2010, 988[VP]

ma.ri′na. L. fem. adj. *marina* of the sea, marine.

Forms a substrate mycelium which undergoes fragmentation. Substrate mycelium is light gray-white on glycerol-asparagine agar (ISP medium 5), moderate reddish-brown on yeast extract-malt extract agar (ISP medium 2), and pale pink on oatmeal (ISP medium 3) and potato agars. Optimal growth occurs on ISP 2 agar prepared without NaCl at 28–37°C and pH 7.0. Growth occurs at 15–45°C, pH 6.0–9.0 and 0–10% (w/v) NaCl. Catalase-positive, but oxidase-negative. Coagulates milk, but is negative for hydrogen sulfide production, nitrate reduction, and starch hydrolysis. L-Alanine, L-histidine, hypoxanthine, L-phenylalanine, L-proline, DL-tryptophan, L-tyrosine, L-valine, and xanthine are used as nitrogen sources, but not adenine or DL-methionine.

Additional phenotypic properties are cited in the text and in Table 253.

Cellular fatty acids contain major proportions of $C_{16:0}$ iso, $C_{16:0}$, and $C_{15:0}$ iso, and smaller proportions (<10%) of $C_{16:1}$ iso H and $C_{17:0}$.

Source: isolated from ocean sediment.

DNA G+C content (mol%): 66.1 (HPLC).

Type strain: CCTCC AA 208056, DSM 45268, MS498.

Sequence accession no. (16S rRNA gene): FJ444996.

7. **Prauserella muralis** Schäfer, Martin and Kämpfer 2010, 289[VP]

mu.ra′lis. L. fem. adj. *muralis* pertaining or belonging to walls.

Forms mycelial-like filaments (1.5 µm), and a white aerial mycelium which undergoes fragmentation. The substrate mycelium is gray to light orange on M79 agar. Grows well on nutrient and tryptone soy agars after 3 d at 25–30°C. Weakly oxidase-positive, but negative for esculin hydrolysis. *p*NP-α-D-Glucopyranoside and *p*NP-β-D-xylopyranoside are hydrolyzed, but not L-alanine-*p*NA, *bis*-*p*NP phosphate, 2-deoxythymidine-5-*p*NP phosphate, *o*NP-β-D-galactopyranoside, *p*NP-glucopyranoside, *p*NP-β-D-glucuronide, L-glutamate-γ-3-carbonyl-*p*NP, *p*NP-phenylphosphate, *p*NP-phosphorylcholine, or L-proline *p*NP.

Additional phenotypic properties are cited in the text or in Table 253.

Cellular fatty acids contain major proportions of $C_{16:0}$ iso; smaller proportions (<10%) of $C_{15:0}$ iso, $C_{15:1}$ ω6*c*, $C_{15:0}$, $C_{16:1}$ iso H, $C_{16:1}$ ω7*c* and/or $C_{15:0}$ iso 2-OH, $C_{16:0}$, $C_{16:0}$ 10-methyl, $C_{17:0}$ iso, $C_{17:0}$ anteiso, $C_{17:1}$ ω8*c*, $C_{17:1}$ ω6*c*, $C_{17:0}$, $C_{17:0}$ 10-methyl, and traces of $C_{14:0}$ iso and $C_{14:0}$ are found.

Source: isolated from the wall of a house colonized with molds.

DNA G+C content (mol%): not determined.

Type strain: 05-Be-005, CCM 7635, CCUG 57426, DSM 45305, NRRL B-24780.

Sequence accession no. (16S rRNA gene): FM956091.

8. **Prauserella salsuginis** Li, Tang, Chen, Wu, Zhi, Zhang and Li 2009b, 2926[VP]

sal.su′gi.nis. L. n. *salsugo -inis* brine, salt water, L. gen. n. *salsuginis* of salt water, from which the type strain was isolated.

Aerobic, Gram-stain-positive actinomycete which forms a substrate mycelium that undergoes fragmentation and produces a white aerial mycelium. Colonies are deep yellow on Czapek's agar, light gray-white on glycerol-asparagine agar (ISP medium 5), pale orange-yellow on nutrient and potato agars, and brilliant yellow on yeast extract-malt extract agar (ISP medium 2). Grows at 15–45°C, pH 6.0–9.0, and 5–15% (w/v) NaCl on ISP 2 medium; optimal conditions are 28–37°C, pH 7.0, and 8–10% NaCl.

Catalase-positive, but oxidase-negative. Coagulates milk, but is negative for melanin and H_2S production.

L-Alanine, L-histidine, L-phenylalanine, L-proline, DL-tryptophan, L-tyrosine, xanthine, and L-valine are used as sole nitrogen sources, but not adenine or DL-methionine.

DNA–DNA relatedness values between the type strain and those of other *Prauserella* species are: *Prauserella aidingensis*, 44.0%; *Prauserella flava*, 56.9%; and *Prauserella sediminis*, 60.3%.

Additional phenotypic properties are cited in the text and in Table 253.

Cellular fatty acids contain major proportions of $C_{16:0}$ iso; smaller proportions (<10%) of $C_{15:0}$, $C_{15:0}$ iso, $C_{15:1}$ B, $C_{16:0}$, $C_{16:0}$ iso 2-OH, $C_{16:1}$ ω9*c*, $C_{16:1}$ iso H, $C_{17:0}$ anteiso, $C_{17:0}$ anteiso 2-OH, $C_{17:1}$ anteiso, and $C_{18:1}$ 2-OH, and traces of $C_{17:1}$ ω9*c* are found.

Source: isolated from a salt lake.

DNA G+C content (mol%): 69.1 (HPLC).

Type strain: CCTCC AA 208051, DSM 45264, YIM 90625.

Sequence accession no. (16S rRNA gene): FJ444992.

9. **Prauserella sediminis** Li, Tang, Chen, Wu, Zhi, Zhang and Li 2009b, 2927[VP]

se.di′mi.nis. L. n. *sedimen -inis* sediment; L. gen. n. *sediminis* of sediment.

Forms a substrate mycelium that undergoes fragmentation and produces a white aerial mycelium on most media. Colonies are deep gray-white on glycerol-asparagine agar (ISP medium 5), pale yellow on oatmeal agar (ISP medium 3), gray-reddish orange on potato agar and orange-yellow on yeast extract-malt extract agar (ISP medium 2). Grows at 15–45°C, pH 6.0–9.0, and 5–20% (w/v) NaCl on ISP 2 medium; optimal conditions are 28–37°C, pH 7.0, and 10% NaCl.

Catalase-positive, but oxidase-negative. Coagulates milk, but is negative for H_2S production, nitrate reduction, and starch hydrolysis.

L-Alanine, L-histidine, L-phenylalanine, L-proline, DL-tryptophan, L-tyrosine, xanthine, and L-valine are used as sole nitrogen sources, but not adenine or DL-methionine.

Additional phenotypic properties are cited in the text and in Table 253.

Cellular fatty acids contain major proportions of $C_{16:0}$ iso; smaller proportions (<10%) of $C_{14:0}$ iso, $C_{15:0}$, $C_{15:0}$ iso, $C_{15:1}$ B, $C_{16:0}$, $C_{16:0}$ 2-OH, $C_{16:1}$ ω9*c*, $C_{16:1}$ iso H, $C_{17:0}$, $C_{17:0}$ iso 2-OH, $C_{17:0}$ anteiso, and $C_{17:1}$ anteiso, and traces of $C_{14:0}$, $C_{17:1}$ ω9*c*, and $C_{17:1}$ 2-OH are found.

Source: isolated from a salt lake.

DNA G+C content (mol%): 69.1 (HPLC).

Type strain: CCTCC AA 208054, DSM 45267, YIM 90694.

Sequence accession no. (16S rRNA gene): FJ444995.

Genus XIII. **Saccharomonospora** Nonomura and Ohara 1971, 899[AL]

Seung Bum Kim

Sac.cha.ro.mon.o.spo′ra. Gr. n. *sakchâr* sugar; Gr. adj. *monos* single, solitary; Gr. fem. n. *spora* seed; N.L. fem. n. *spora* a spore; N.L. fem. n. *Saccharomonospora* the sugar (-containing) single-spored (organism).

Gram-stain-positive, aerobic, and chemo-organotrophic. **Produces single or paired spores on aerial hyphae.** Spores may be formed on substrate mycelium. The aerial mycelium can be white, yellow-white, green, or light to dark blue; green pigmentation may also occur on the vegetative mycelium and diffuse into the surrounding medium. **Substrate mycelia are rarely fragmented**. Spores in pairs or short chains on vegetative or aerial hyphae are occasionally present. **The cell wall contains *meso*-diaminopimelic acid (*meso*-DAP), and the sugars arabinose and galactose (wall chemotype IV).** Mycolic acids are absent. Major amounts of iso- and anteiso- fatty acids are found; the main **menaquinone is MK-9(H_4)**. The diagnostic phospholipid is **phosphatidylethanolamine** (**phospholipid type II**), but some species may also contain glucosamine-containing phospholipids (type IV). **Mesophilic or thermophilic**; growth occurs between 24 and 60°C, and at neutral pH. **NaCl may be required for growth.** Isolated from soil, lake sediments, marsh soil, peat, manure, compost, and overheated fodder.

DNA G+C content (mol%): 68–74.

Type species: **Saccharomonospora viridis** (Schuurmans, Olson and San Clemente 1956) Nonomura and Ohara 1971, 899[AL] [*Thermoactinomyces viridis* Schuurmans, Olson and San Clemente 1956, 61; *Thermomonospora viridis* (Schuurmans, Olson and San Clemente 1956) Küster and Locci 1963].

Further descriptive information

Phylogeny. *Saccharomonospora* is phylogenetically related to the genera *Prauserella* and *Thermocrispum* (Kim and Goodfellow, 1999; Labeda and Kroppenstedt, 2006). In 16S rRNA gene sequence analyses, the species are divided into two main cluster groups, one including *Saccharomonospora azurea*, *Saccharomonospora cyanea*,

FIGURE 313. Aerial spores of *Saccharomonospora azurea* strain NA-128[T]. Magnification 4800×. (Reproduced with permission from Hu, 1997. Int. J. Syst. Bacteriol. *47*: 60–61.)

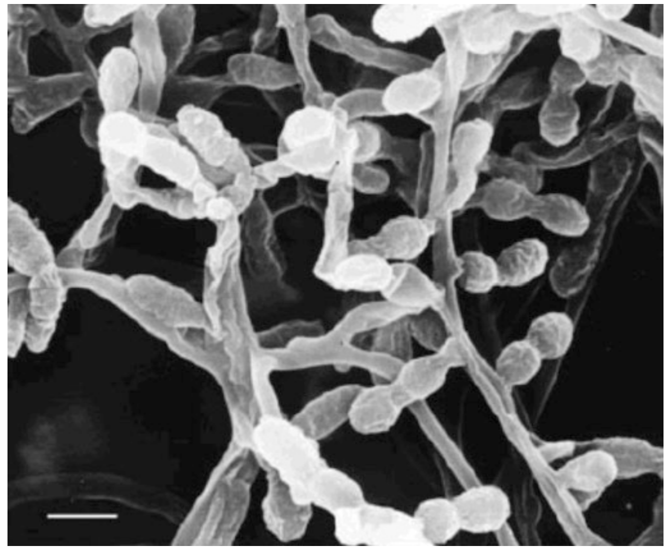

FIGURE 314. Aerial spore of *Saccharomonospora halophila* strain 8[T]. Bar = 1 µm. (Reproduced with permission from Al-Zarban et al., 2002. Int. J. Syst. Evol. Microbiol. *52*: 555–558.)

Saccharomonospora glauca, *Saccharomonospora viridis*, and *Saccharomonospora xinjiangensis*, and the other including *Saccharomonospora halophila*, *Saccharomonospora marina*, *Saccharomonospora paurometabolica*, and *Saccharomonospora saliphila*, respectively (Al-Zarban et al., 2002; Li et al., 2003b; Syed et al., 2008; Liu et al., 2010). The 16S rRNA gene sequence similarity among the type strains ranges from 95.2 to 98.5%. The levels of DNA–DNA relatedness between the type strain of *Saccharomonospora saliphila* and those of *Saccharomonospora azurea*, *Saccharomonospora halophila*, and *Saccharomonospora paurometabolica* were reported as 46.0, 41.0, and 42.5%, respectively (Syed et al., 2008). The value between *Saccharomonospora paurometabolica* and *Saccharomonospora halophila* was 53.8% (Li et al., 2003b).

Cellular morphology. The aerial and vegetative mycelia are well developed and irregularly branched. The substrate mycelium is, in most cases, non-fragmented. Aerial mycelium is generally abundant, but can be absent in some strains. The color of aerial mycelia is green to blue, except for *Saccharomonospora paurometabolica* and *Saccharomonospora xinjiangensis* which is white, orange-white, or yellow-white. Single spores are borne at the tip of aerial hyphae in most species (Figure 313), but spores in longitudinal pairs are also produced in *Saccharomonospora marina*, *Saccharomonospora saliphila* and *Saccharomonospora xinjiangensis* (Figure 314).The spores are ovoid, ellipsoidal, or round (0.7–1.1 × 1.0–1.8 µm); the surface of individual spores is smooth for *Saccharomonospora azurea*, *Saccharomonospora marina*, *Saccharomonospora paurometabolica*, *Saccharomonospora saliphila*, and *Saccharomonospora xinjiangensis*, and warty for the remaining four species. Wrinkled spores may be observed for *Saccharomonospora marina*, *Saccharomonospora paurometabolica* and *Saccharomonospora saliphila*. The spores of *Saccharomonospora viridis* are not viable at temperatures above 70°C.

Nutrition and growth conditions. Strains of *Saccharomonospora glauca*, *Saccharomonospora viridis*, and *Saccharomonospora xinjiangensis* are thermotolerant, preferring temperatures of 45–50°C, whereas the remaining species are mesophilic. *Saccharomonospora halophila* and *Saccharomonospora paurometabolica* require NaCl for growth, but *Saccharomonospora cyanea*, *Saccharomonospora glauca*, *Saccharomonospora viridis*, and *Saccharomonospora xinjiangensis* cannot grow in the presence of 5% (w/v) NaCl. *Saccharomonospora azurea* and *Saccharomonospora saliphila* do not require NaCl for growth, but the former can grow in the presence of up to 7%, and the latter in up to 20% (w/v) concentration.

Cell-wall composition. Phosphatidylethanolamine is the main phospholipid for all species and, in addition, hydroxyphosphatidylethanolamine, lysophosphatidylethanolamine, phosphatidylinositol, phosphatidylglycerol, and diphosphatidylglycerol are variably found (corresponding to the type II phospholipid pattern *sensu* Lechevalier et al., 1981). However, *Saccharomonospora xinjiangensis* contains phosphatidylcholine and glucosamine-containing phospholipid in addition to phosphatidylethanolamine, exhibiting a type IV phospholipid pattern. The fatty acid profile is highly variable among species, but is generally a mixture of branched and straight chain saturated or unsaturated fatty acids, with smaller amounts of hydroxylated fatty acids. The main menaquinone is MK-9(H_4), whereas MK-8(H_4), MK-9(H_2), and MK-7(H_4) are variably present as minor components.

Ecology. Saccharomonosporae occur in a wide range of natural or synthetic habitats including soil (Al-Zarban et al., 2002; Jin et al., 1998; Li et al., 2003b; Syed et al., 2008), compost (Amner et al., 1988; Dees and Ghiorse, 2001; Song et al., 2001; Steger et al., 2007), plant materials (Abdulla and El-Shatoury, 2007; Gangwar et al., 1989; Roussel et al., 2005; Unaogu et al., 1994; Liu et al., 2010), marine sediment (Maldonado et al., 2009), and marine sponge (Selvin et al., 2009). Compost is clearly a preferred habitat for thermophilic *Saccharomonospora* (Dees and Ghiorse, 2001; Khan et al., 1995; Song et al., 2001; Unaogu et al., 1994).

Other properties. *Saccharomonospora viridis* is strongly implicated as one of the causative agents of hypersensitivity

pneumonitis including farmer's lung disease (Greene et al., 1981; Harvey et al., 2001; Roberts et al., 1976; Treuhaft et al., 1980; Wenzel et al., 1974). Strains of *Saccharomonospora viridis*, *Saccharomonospora glauca*, "*Saccharomonospora caesia*", and "*Saccharomonospora internatus*" display antibiotic activities against Gram-stain-positive bacteria (Greiner-Mai et al., 1988). *Saccharomonospora viridis* is known to produce thermoviridin (Schuurmans et al., 1956). Many strains of *Saccharomonospora* produce degradative enzymes for natural or anthropogenic compounds, such as polyester, rice straw, mushroom compost, synthetic food waste compost, proteins, and starch (Abdulla and El-Shatoury, 2007; Collins et al., 1992; Dolashka et al., 1998; Song et al., 2001; Tseng et al., 2007).

Enrichment and isolation procedures

Mesophilic saccharomonosporae are present in soils, leaf litter, and manure; thermophilic strains can be found in compost, while marsh soils are a good source for halophilic strains. Conventional methods for the isolation of actinobacteria can be used for the isolation of saccharomonosporae, but improved recovery has been reported using selective isolation methods, such as dry heat treatment, addition of antibiotics to the isolation medium, use of sedimentation chamber with an Andersen air sampler, and a combination of the above methods (Amner et al., 1989; Andersen, 1958; Athalye et al., 1981; Kim et al., 1995; Nonomura and Ohara, 1971).

The isolation media include modified glycerol-asparagine agar [ISP medium 5 supplemented with 20% (w/v) NaCl] half-strength tryptone-soy agar, HV agar (Hayakawa, 1990), and R8 agar (Amner et al., 1989). For the prevention of fungal growth, antibiotics such as cycloheximide (50 µg/ml) may be added to the media.

Maintenance procedures

The following media can be used for the cultivation and maintenance of *Saccharmonospora* isolates: yeast extract-malt extract (ISP 2) agar, inorganic salts-starch (ISP 4) agar, Czapek–Dox yeast extract-Casamino acids (CYC) agar (Cross and Attwell, 1974), starch-nitrate agar with 10% (w/v) NaCl (Al-Zarban et al., 2002), and tryptic soy agar (TSA). *Saccharomonospora halophila* and *Saccharomonospora paurometabolica* require NaCl for growth at an optimal concentration of 10% (w/v). For long-term storage, spores and mycelial fragments are suspended in 10–20% (v/v) aqueous glycerol and stored at −20°C, or lyophilized.

Differentiation of the genus *Saccharomonospora* from other genera

Saccharomonospora can be distinguished from other members of the family *Pseudonocardiaceae* by the production of single spores on aerial hyphae. Fragmentation of the substrate mycelium is rarely observed, which is an important differential feature of the genus from closely related genera, including *Prauserella*, *Saccharopolyspora*, and *Thermoscrispum*. Sporangia-like structures have not been observed in *Saccharomonospora*, in contrast to *Crossiella*, *Kibdelosporangium*, *Kutzneria*, *Streptoalloteichus*, and *Thermocrispum*. The phospholipid pattern of *Saccharomonospora* is type II, with the exception of *Saccharomonospora xinjiangensis* (type IV), whereas that of *Saccharopolyspora* is type III.

Taxonomic comments

The genus *Saccharomonospora* currently contains nine species with validly published names (Figure 315). The type species *Saccharomonospora viridis* Nonomura and Ohara 1971 was first

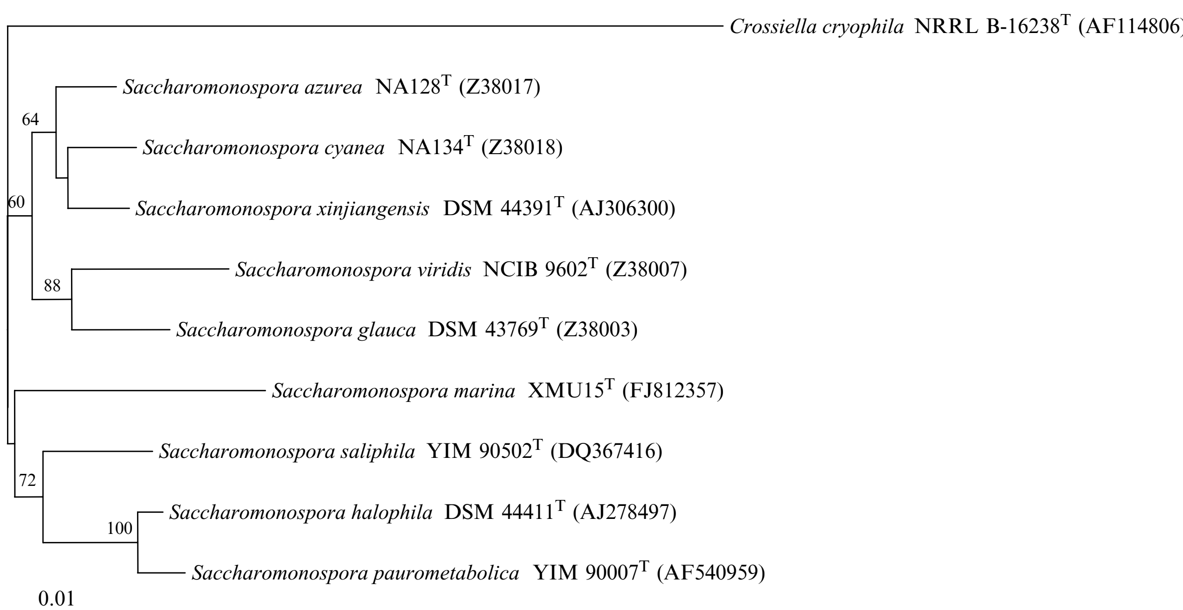

FIGURE 315. Phylogenetic tree of the genus *Saccharomonospora* based on 16S rRNA gene sequences. The Jukes–Cantor model was used in the estimation of evolutionary distances and neighbor-joining method was used for tree construction. Numbers at nodes indicate levels of bootstrap support (%). Bar = 0.01 substitutions per nucleotide position.

proposed as "*Thermoactinomyces viridis*" by Schuurmans et al. (1956), and later reclassified as "*Thermomonospora viridis*" Küster and Locci 1963. *Saccharomonospora* was then proposed based on morphological and chemotaxonomic criteria (Nonomura and Ohara, 1971), which was further supported by numerical phenetic data (Goodfellow and Pirouz, 1982; McCarthy and Cross, 1984).

Phylogenetic studies on saccharomonosporae have been conducted using analysis of 16S rRNA gene sequences (Kim et al., 1995), internally transcribed spacer sequences of 16S–23S and 23S–5S rRNA genes (Yoon et al., 1997), and ribonuclease P (RNase P) RNA gene sequences (Cho et al., 1998). These data constantly suggested that "*Saccharomonospora caesia*" was a synonym of *Saccharomonospora azurea*. Additionally, DNA–DNA relatedness studies among the representative species of *Saccharomonospora* were also carried out (Yoon et al., 1999), confirming the former proposal. Ruan et al. (1994) used partial sequences of the 23S rRNA gene for the classification of *Saccharomonospora* and related taxa.

DNA–DNA hybridization data also confirmed that "*Saccharomonospora internatus*" (Greiner-Mai et al. 1987; Kurup 1981), formerly "*Micropolyspora internatus*" Agre et al. 1974, is a synonym of *Saccharomonospora viridis* Greiner-Mai et al. 1988, as the two taxa exhibited 90% DNA–DNA relatedness (Yoon et al., 1999).

A PCR-based method for the rapid detection of *Saccharomonospora* isolates has been developed using a set of genus-specific primers (Salazar et al., 2000). The sequence data indicate that these oligonucleotide primers are also applicable to the species that have been described subsequently, namely *Saccharomonospora halophila*, *Saccharomonospora paurometabolica*, and *Saccharomonospora xinjiangensis*. In another study, a rapid detection method based on fluorescence *in situ* hybridization (FISH) using 16S rRNA-targeted oligonucleotide probes was developed for the specific detection of *Saccharomonospora* spp. (Neef et al., 2003).

The primycin-producing actinobacterium, initially described as "*Thermomonospora galeriensis*" (Szabo et al., 1976), was reported to produce single spores and dark green aerial mycelium. This species contains a type IV cell wall and was considered to be a member of the genus *Saccharomonospora* by McCarthy and Cross (1984), but its correct taxonomic position needs to be clarified.

The strains known as "*Thermoactinomyces glaucus*" IFO 12530 (Henssen, 1957) and "*Thermoactinomyces monosporus*" IFO 14050 (Waksman and Cork, 1953) have been assigned to *Saccharomonospora glauca* based on chemotaxonomic and genotypic characterization (Yoon et al., 2000; Yoon and Park, 2000).

Differentiation of the species of the genus *Saccharomonospora*

The species of *Saccharomonospora* can be separated from one another by a combination of physiological and chemotaxonomic properties. *Saccharomonospora paurometabolica* produces white aerial mycelium, *Saccharomonospora xinjiangensis* yellow-white and *Saccharomonospora saliphila* gray-red, whereas most others produce blue to green aerial mycelia. The warty spore surface separates *Saccharomonospora cyanea*, *Saccharomonospora glauca*, *Saccharomonospora halophila*, and *Saccharomonospora viridis* from the remaining species. Unlike other species, *Saccharomonospora halophila* and *Saccharomonospora paurometabolica* can grow in the presence of up to 30% NaCl, but cannot grow without NaCl. Other differential properties are listed in Table 254.

List of species of the genus *Saccharomonospora*

1. **Saccharomonospora viridis** (Schuurmans, Olson and San Clemente 1956) Nonomura and Ohara 1971, 899[AL] [*Thermoactinomyces viridis* Schuurmans, Olson and San Clemente 1956, 61; *Thermomonospora viridis* (Schuurmans, Olson and San Clemente 1956) Küster and Locci 1963]. Subjective synonym: "*Saccharomonospora internatus*" (Agre et al. 1974) Greiner-Mai, Korn-Wendisch and Kutzner 1988.

   vir′i.dis. L. fem. adj. *viridis* green.

   Single spores are mainly produced on aerial mycelium, but short chains of spores may also be formed. The spores are heat-sensitive. Vegetative mycelia are branched and may produce spores. Leathery colonies are formed on agar media, with aerial hyphae covered by densely packed spores. Aerial mycelium is initially white, becoming gray-green to dark green. The aerial spore mass may be non-pigmented or lilac-colored. Vegetative mycelium may be green. Production of a green diffusible pigment is also observed. Amino acid and vitamin supplements (e.g. yeast extract) are required for good growth. Catalase, deaminase, and phosphatase are produced. Casein, gelatin, starch, xylan, and tyrosine are degraded, but not cellulose. A number of organic compounds can serve as sole sources of carbon, and the utilization of glycerol is characteristic. Optimal growth occurs at 35–50°C and pH 7.0–10. Growth occurs in the presence of up to 3% (w/v) NaCl, but not at concentrations of 5% or higher.

   Source: manure, compost, overheated fodder, soil, lake sediments, peat.

   DNA G+C content (mol%): 69–74 (T_m).

   Type strain: ATCC 15386, CCUG 5913, DSM 43017, JCM 3036, NBRC 12207, NCIB 9602, NRRL B-3044, VKM Ac-681.

   Sequence accession no. (16S rRNA gene): Z38007.

2. **Saccharomonospora azurea** Hu 1987, 61[VP]

   Subjective synonym: "*Saccharomonospora caesia*" (Kalakoutskii 1964) Greiner-Mai, Kroppenstedt, Korn-Wendisch and Kutzner 1987.

   a.zu.re′a. N.L. fem. adj. *azurea* azure, referring to the color of the aerial mycelium.

Substrate mycelium is non-fragmenting. Sporangia are not produced. Single spores are borne mainly on the aerial mycelium. Spores are oval or round, 0.8 to 1.0 µm. Sporophores are very short or sessile. Spore surface is smooth. The color of the aerial mycelium is azure on oatmeal and Czapek–Dox sucrose agars. No distinct soluble pigment is formed. D-Fructose, D-glucose, glycerol, lactose, maltose, mannose, melibiose, raffinose, L-rhamnose, ribose, sucrose, trehalose, and D-xylose are utilized as sole carbon sources, but not L-arabinose, galactose, inositol, or D-mannitol. Growth occurs between 24 and 40°C.

Source: soil.

DNA G+C content (mol%): not determined.

Type strain: NA-128, ATCC 43670, DSM 44631, JCM 7551, NBRC 14651, SIIA 86128.

Sequence accession no. (16S rRNA gene): Z38017.

3. **Saccharomonospora cyanea** Hu, Cheng and Wei 1988, 445[VP]

cy.a′ne.a. L. fem. adj. *cyanea* dark blue, referring to the color of aerial mycelium.

Substrate mycelium is non-fragmenting. No sporangium is observed. Single spores are borne mainly on aerial mycelium. Spores are oval to ellipsoidal (0.8–1.0 ×1.0–1.8 µm). Sporophores are very short or sessile. The color of the aerial mycelium is light to dark blue on various agar media. No distinct soluble pigment is formed. D-Fructose, glycerol, lactose, maltose, mannose, raffinose, L-rhamnose, ribose, sucrose, trehalose, and D-xylose are utilized as sole carbon sources, but not L-arabinose, D-glucose, *i*-inositol, D-mannitol, or melibiose. The temperature range for growth is between 24 and 40°C; optimal growth occurs between 28 and 37°C.

Source: soil.

DNA G+C content (mol%): not determined.

Type strain: NA-134, ATCC 43724, DSM 44106, JCM 7552, NBRC 14841, SIIA 86134.

Sequence accession no. (16S rRNA gene): Z38018.

4. **Saccharomonospora glauca** Greiner-Mai, Korn-Wendisch and Kutzner 1988, 403[VP]

glau′ca. L. fem. adj. *glauca* bluish, greenish, grayish blue, referring to the color of the aerial mycelium.

Branching, non-fragmenting aerial and substrate mycelia are formed. Single spores are produced tightly packed on the aerial hyphae. Spores are smooth or slightly roughened, round to oval, and 0.8 to 1.0 µm in diameter. Colonies produce light green to bluish green (turquoise) aerial mycelium, dark green substrate mycelium, and soluble pigment on glycerol-cornsteep (GC) and glycerol-yeast extract-malt extract (GYM) agars. The temperature range for growth is 37–60°C and the optimum temperature is 50°C. Strains are sensitive to lysozyme (200 U/ml) and tolerant to 7% (w/v) NaCl. No melanin is produced. Tyrosine, starch, triglycerides, blood cells (hemolysis), casein, collagen, and esculin are degraded. Arabinose, dextrin, D-glucose, and mannitol are used as sole carbon sources. Antibiotic activity is displayed against Gram-stain-positive bacteria.

All strains of *Saccharomonospora glauca* are sensitive to phage ϕ771 and, in addition, several strains are sensitive to phage ϕL1g. All strains are resistant to the Tm_1 family of phages, which is specific for *Saccharomonospora viridis*. All strains show identical total protein and DNA restriction patterns; esterase pattern III (four main bands) is found. The R_f value of malate dehydrogenase is 0.50.

Source: moldy hay, soil, compost, and manure.

DNA G+C content (mol%): not determined.

Type strain: K62, DSM 43769, JCM 7444, NBRC 14831.

Sequence accession no. (16S rRNA gene): Z38003.

5. **Saccharomonospora halophila** Al-Zarban, Al-Musallam, Abbas, Stackebrandt and Kroppenstedt 2002, 557[VP]

ha.lo.phi′la. L. n. *hals, halos* salt; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *halophila* salt-loving, referring to the ability to grow at high NaCl concentration.

Light blue aerial mycelium is produced. Specific endo- or exo-pigments are not observed. Optimal growth is obtained on starch-nitrate agar supplemented with 10% (w/v) NaCl at 28°C. Grows in the presence of 10–30% NaCl. Feathers can be utilized as sole C and N source in the presence of 10% (w/v) NaCl. L-Arabinose, D-galactose, D-glucose, mannitol, mannose, melibiose, and L-rhamnose are utilized as sole carbon sources, but not D-xylose. The utilization of D-ribose is doubtful. Major cellular fatty acids are $C_{16:0}$ iso (22.5%), $C_{16:0}$ (15.8%), and $C_{16:1}$ (14.1%).

Source: salt marsh soil.

DNA G+C content (mol%): not determined.

Type strain: strain 8, DSM 44411, JCM 11761, NRRL B-24125.

Sequence accession no. (16S rRNA gene): AJ278497.

6. **Saccharomonospora marina** Liu, Li, Zheng, Huang and Li 2010, 1856[VP]

ma.ri′na. L. fem. adj. *marina* of the sea.

Nonmotile smooth or wrinkled spores are produced on the branched aerial mycelium singly, in pairs and occasionally in short chains. Optimal growth occurs at 28–37°C and at pH 7.0 on ISP medium 2. Growth occurs in the presence of up to 5% NaCl (w/v), with an optimum concentration of 0–3% (w/v). D-Arabinose, cellobiose, D-galactose, D-glucose, *myo*-inositol, maltose, D-mannitol, D-mannose, melibiose, L-rhamnose, sucrose and D-xylose are utilized as carbon sources, but not lactose, sorbitol, L-sorbose, raffinose and ribose. L-Alanine, L-arginine, L-cystine, L-glutamate, glycine, L-leucine, L-lysine, L-methionine, L-phenylalanine, L-proline, L-serine, L-threonine, L-tyrosine and L-valine are used as nitrogen sources, but not DL-asparagine, L-histidine, L-hydroxyproline and DL-tryptophan. Gelatin liquefaction, milk coagulation and nitrate reduction are positive, but cellulose and starch hydrolysis, hydrogen sulfide and melanin production are negative. Catalase, urease and oxidase activities are negative. Resistant to ampicillin (10 mg), carbenicillin (10 mg), cefuroxime (30 mg), ceftriaxone (30 mg), cephalothin (V) (30 mg), cephalothin (VI) (30 mg), chloramphenicol (30 mg), furoxone (30 mg), penicillin (10 mg), piperacillin (10 mg) and oxacillin (1 mg), but not to cephalothin (IV) (300 mg) and fortum (30 mg).

Major cellular fatty acids are $C_{16:0}$ iso (26.3%), $C_{17:1}$ ω6*c* (16.8%), $C_{15:0}$ (15.2%), $C_{16:0}$ (8.9%), $C_{17:1}$ ω8*c* (7.7%), and $C_{16:1}$ iso H (6.0%).

Habitat: ocean sediment.

DNA G+C content (mol%): 68.1 (HPLC).

Type strain: XMU15, KCTC 19701, CCTCC AA 209048.

Sequence accession no. (16S rRNA gene): FJ812357.

7. **Saccharomonospora paurometabolica** Li, Tang, Stackebrandt, Kroppenstedt, Schumann, Xu and Jiang 2003b, 1593[VP]

pau.ro.me.ta.bo′li.ca. Gr. adj. *pauros* little; Gr. adj. *metabolikos* changeable; N.L. fem. adj. *paurometabolica* little changeable, referring to the poor utilization of carbon sources.

Aerial mycelium is well developed on yeast extract-malt extract agar, glycerol-asparagine agar, nutrient agar, and Czapek's agar; moderate on oatmeal agar and poor on inorganic salts-starch agar and potato agar. White aerial mycelium is produced on all media except on nutrient agar where it is green-yellow. Sporulation is good on ISP 2, ISP 5, nutrient agar, and Czapek's agar, and moderate on ISP 3 agar, but poor on ISP 4 agar. Substrate mycelium is well developed on most media tested. The color of the substrate mycelium is deep orange-yellow (ISP 2), light yellow-brown (nutrient agar), light yellow-orange (potato agar), or white (ISP 4, ISP 5, and Czapek's agar). Nonmotile, single spores with smooth or wrinkled surface are borne on either the aerial or substrate mycelium. Optimum growth temperature is 35–37°C. Optimum NaCl concentration for growth is 10% (w/v). Nitrate is reduced. Milk peptonization and coagulation, gelatin liquefaction, growth in cellulose, H_2S and melanin production, starch hydrolysis, and urease production are not observed. Major cellular fatty acids are $C_{18:1}$ (44.3%), $C_{16:0}$ (20.7%), and $C_{16:0}$ iso (11.2%).

Source: saline soil.

DNA G+C content (mol%): 71 (T_m).

Type strain: BCRC (formerly CCRC) 16315, CCTCC AA 001018, DSM 44619, JCM 13241, YIM 90007.

Sequence accession no. (16S rRNA gene): AF540959.

8. **Saccharomonospora saliphila** Syed, Tang, Cai, Zhi, Agasar, Lee, Kim, Jiang, Xu and Li 2008, 572[VP]

sa.li′phi.la. L. n. *sal*, *salis* salt; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *saliphila* salt-loving.

Aerial mycelium is well developed on yeast extract-malt extract agar (ISP 2), inorganic salts-starch agar (ISP 4), glycerol-asparagine agar (ISP 5), potato agar, and Czapek's agar; no growth is observed on oatmeal agar (ISP 3) or nutrient agar. Grayish to reddish-gray aerial mycelium is produced on the above media. Good sporulation is observed on ISP 2, ISP 4, ISP 5, potato agar, and Czapek's agar. Substrate mycelium is well developed on most media tested. The color of substrate mycelium is grayish red on Czapek's agar, dark red on ISP 2 and ISP 5, and blackish red on ISP 4 and potato agar. Nonmotile, single or pairs of spores with smooth or wrinkled surfaces are borne on aerial mycelium. Optimum growth temperature is 28°C; grows well at temperatures up to 40°C. Optimum growth is observed in 10% (w/v) NaCl, although it is not essential for growth. H_2S is produced. Milk peptonization and coagulation, gelatin liquefaction, growth in cellulose, melanin production, starch hydrolysis, and urease production are not observed. Cellobiose, fructose, D-galactose, D-glucose, maltose, raffinose, sorbitol, sucrose, and D-xylose are utilized as sole carbon sources, but not L-arabinose, *myo*-inositol, lactose, mannitol, rhamnose, trehalose, or xylitol. Major cellular fatty acids are $C_{16:0}$ iso (49.2%), $C_{17:1}$ ω6*c* (9.1%), $C_{15:0}$ (5.4%), and $C_{16:1}$ iso OH (5.0%).

Source: muddy soil.

DNA G+C content (mol%): 71.8 (T_m).

Type strain: DSM 45087, KCTC 19234, YIM 90502.

Sequence accession no. (16S rRNA gene): DQ367416.

9. **Saccharomonospora xinjiangensis** Jin, Xu, Mao, Hseu and Jiang 1998, 1097[VP]

xin.ji.ang.en′sis. N.L. fem. adj. *xinjiangensis* pertaining to Xinjiang, a province of north-west China.

Yellow-white aerial mycelium is formed on ISP 2, ISP 3, and nutrient agar (light green-gray on Czapek's agar), and the vegetative mycelium is light yellowish. The sporulation of both aerial and vegetative mycelia is good on most media tested. Spores are borne in longitudinal pairs on vegetative hyphae, and in longitudinal pairs (or in a few cases singly) on aerial hyphae. Light yellow-brown diffusible pigment is produced on potato extract-glucose agar, but melanin pigment is not produced on tyrosine agar. Adonitol, cellobiose, fructose, inositol, inulin, mannitol, raffinose, rhamnose, and xylose are utilized, but no acid is produced from these carbon sources. Alanine, histidine, and proline are utilized. Starch, cellulose, and lecithin are degraded. Hydrogen sulfide is produced. Autolysis of aerial hyphae is observed on yeast extract-malt extract agar and nutrient agar. Growth occurs between 45 and 50°C. Unlike other species of the genus, the phospholipid pattern is type IV, containing phosphatidylcholine and glucosamine-containing phospholipids in addition to phosphatidylethanolamine.

Source: soil.

DNA G+C content (mol%): not determined.

Type strain: XJ-54, CCTCC AA 97021, DSM 44391, JCM 11270.

Sequence accession no. (16S rRNA gene): AJ306300.

Genus XIV. **Saccharopolyspora** Lacey and Goodfellow 1975, 76[AL] emend. Korn-Wendisch, Kempf, Grund, Kroppenstedt and Kutzner 1989, 438

Seung Bum Kim and Michael Goodfellow

Sac.cha.ro.po.ly.spo′ra. N.L. n. *Saccharum* generic name of sugar cane; Gr. adj. *polus* many; Gr. n. *spora* a seed, and in biology a spore; N.L. fem. n. *Saccharopolyspora* the many spored (organism) from sugar cane.

Aerobic, Gram-stain-positive, non-acid-fast, nonmotile, catalase-positive actinobacteria which form an extensively branched substrate mycelium **that typically fragments into coccoid and/or rod-shaped elements**. In some species, the substrate hyphae remain intact or are partially transformed into chains of spores. **Aerial hyphae, when present, generally differentiate into bead-like chains of spores contained within a smooth sheath.** Spores are borne in straight, flexuous, hooked, looped, or spiral chains.

Spore surfaces can be hairy, smooth, spiny, rough, or warty. Substrate mycelia may be buff, brownish red, orange, or yellow and aerial mycelia are white to gray or pinkish white. Diverse compounds are used as sole carbon sources for energy and growth. **Whole-organism hydrolysates contain *meso*-diaminopimelic acid, arabinose, and galactose. Muramic acid moieties are *N*-acetylated. Cells contain tetrahydrogenated menaquinones with nine isoprene units as the predominant menaquinone, phosphatidylcholine, phosphatidylethanolamine, and phosphatidylmethylethanolamine as major polar lipids, and fatty acid profiles rich in iso- and anteiso-branched chain components, but lack mycolic acids.** The phylogenetic position of *Saccharopolyspora*, as determined by 16S rRNA gene sequencing, is in the family *Pseudonocardiaceae*.

DNA G+C content (mol%): 66–77.

Type species: **Saccharopolyspora hirsuta** Lacey and Goodfellow 1975, 78[AL].

Further descriptive information

Phylogeny. The genus *Saccharopolyspora* forms a distinct line of descent in the 16S rRNA *Pseudonocadiaceae* tree (Labeda et al., 2010a; Lu et al., 2001). The relationships between *Saccharopolyspora* species with validly published names are shown in Figure 316. The two most closely related taxa, *Saccharopolyspora hirsuta* subsp. *kobensis* and *Saccharopolyspora jiangxiensis*, share a 16S rRNA gene sequence similarity of 99% and the two most distantly related species, *Saccharopolyspora erythraea* and *Saccharopolyspora thermoflava*, share a similarity of 92%.

Cell morphology. Most saccharopolysporae, like the well-studied type strains of *Saccharopolyspora hirsuta* and *Saccharopolyspora rectivirgula* (formerly *Faenia rectivirgula*), form an extensively branched substrate mycelium, carrying aerial hyphae (Lacey, 1989a, 1989c; Locci, 1976). In *Saccharopolyspora hirsuta*, some substrate hyphae, like those of *Nocardia* strains, fragment into chains of cells in angular opposition (Figure 317), whereas others remain stable (Figure 318). Fragmented hyphae are most abundant in older parts of cultures, although they usually occur together with sterile hyphae. Substrate hyphae remain intact in some species such as *Saccharopolyspora halophila* (Tang et al., 2009a) and *Saccharopolyspora tripterygii* (Li et al., 2009a). In *Saccharopolyspora rectivirgula*, branching of the substrate hyphae is almost at right angles with chains of spores, mostly on short unbranched lateral and terminal sporophores (Figure 319). The developmental micromorphology of the organism has been studied by Locci (1976).

Aerial hyphae which differentiate into chains of spores are typical of *Saccharopolyspora* strains, as illustrated in Figure 320 and Figure 321. The spores of some species, such as *Saccharopolyspora hirsuta*, *Saccharopolyspora hordei*, and *Saccharopolyspor aspinosa*, are separated by lengths of apparently empty hyphae giving a characteristic bead-like appearance (Goodfellow et al., 1989b; Lacey and Goodfellow, 1975; Mertz and Yao, 1990). The spore chains of *Saccharopolyspora hirsuta* may be straight but are usually in loops or spirals (Korn-Wendisch et al., 1989; Lacey and Goodfellow, 1975). In contrast, straight to flexuous chains of 6–10 spores are seen in *Saccharopolyspora jiangxiensis*

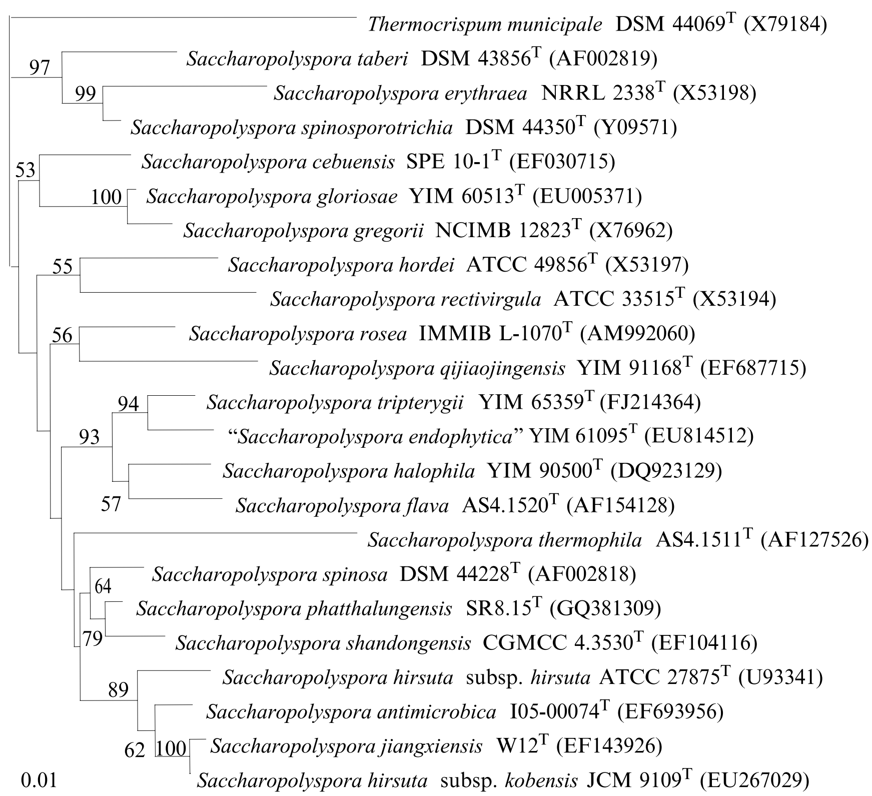

FIGURE 316. Neighbor-joining tree (Saitou and Nei, 1987) based on nearly complete 16S rRNA gene sequences showing relationships between *Saccharopolyspora* species. Numbers at the nodes indicate levels of bootstrap support (Felsenstein, 1985) based on an analysis of 1000 resampled datasets. Only values over 50% are given. Bar = 0.01 substitutions per nucleotide position.

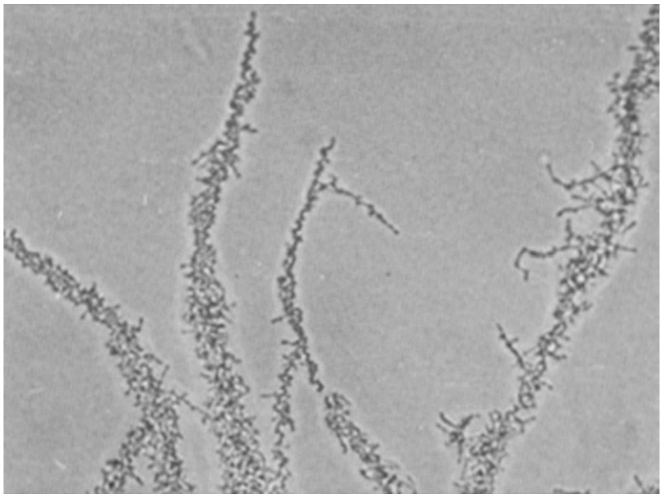

FIGURE 317. Fragmentation of substrate mycelium of *Saccharopolyspora hirsuta*. Glycerol-asparagine agar, incubation 40°C (500×). (Reproduced with permission from Lacey and Goodfellow, 1975. J. Gen. Microbiol. *88*: 75–85.)

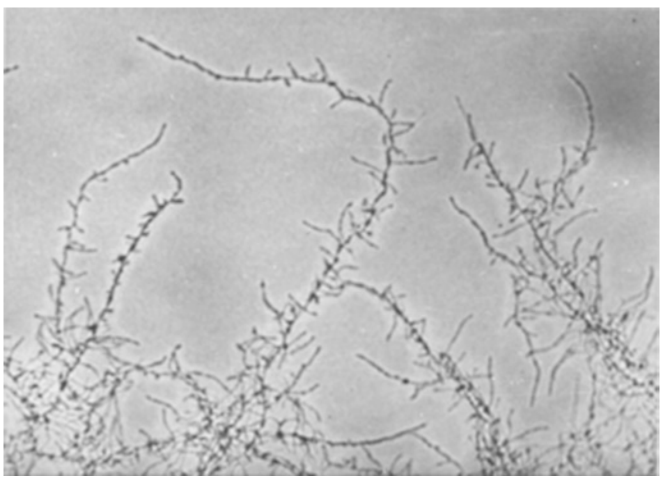

FIGURE 318. Morphology of substrate mycelium of *Saccharopolyspora hirsuta*. Glycerol-asparagine agar, incubation 40°C (550×). (Reproduced with permission from Lacey and Goodfellow, 1975. J. Gen. Microbiol. *88*: 75–85.)

(Zhang et al., 2009), hooked or flexuous chains of 4–6 spores in *Saccharopolyspora thermoflava* (Lu et al., 2001), spiral chains in *Saccharopolyspora spinosporotrichia* (Zhou et al., 1998), and short, straight chains in *Saccharopolyspora rectivirgula* (Figure 322).

Most *Saccharopolyspora* species have spores with smooth surfaces (Table 255). However, ornamented spores are not uncommon, as exemplified by the presence of hairy spores in *Saccharopolyspora hirsuta* (Lacey and Goodfellow, 1975), spiny spores in *Saccharopolyspora shandongensis* (Zhang et al., 2008b), warty spores in *Saccharopolyspora spinosporotrichia* (Zhou et al., 1998), and rough spores in *Saccharopolyspora rectivirgula*, as shown in Figure 322. Spores may be spherical as in *Saccharopolyspora spinosporotrichia* (Zhou et al., 1998), round to oval as in *Saccharopolyspora hirsuta* (Lacey and Goodfellow, 1975), or vesicular as shown by *Saccharopolyspora thermophila* (Lu et al., 2001). The spores of some species are covered by a sheath, as in *Saccharopolyspora gregorii*, *Saccharopolyspora hirsuta*, *Saccharopolyspora hordei*, and *Saccharopolyspora spinosa* (Goodfellow et al., 1989b; Lacey and Goodfellow, 1975; Mertz and Yao, 1990).

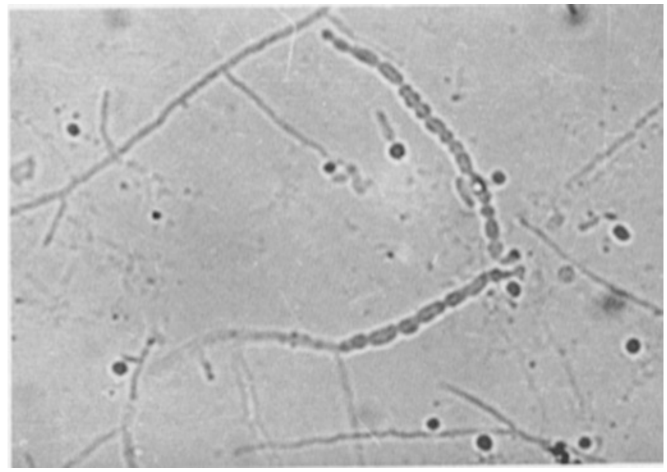

FIGURE 322. Scanning electron micrographs of (A) sporulating hyphae (3000×) and (B) spores (13,000×) of *Saccharopolyspora rectivirgula.*

Fine structure. In general, studies on *Saccharopolyspora hirsuta* and *Saccharopolyspora rectivirgula* show that their cell-wall structure resembles that of other actinobacteria (Lacey, 1989c; Lacey and Goodfellow, 1975). In thin section, *Saccharopolyspora hirsuta* hyphae (Figure 323) are bound by a wall 22–30 nm thick. Within this, a typical unit membrane encloses granular cytoplasm with axial diffuse nuclear material. Electron-transparent vacuoles, up to 0.3 µm in diameter and resembling lipid accumulations in other filamentous actinobacteria which undergo fragmentation (Williams et al., 1976), are sometimes abundant. Also occasionally present are electron-dense granules, up to 0.1 µm in diameter, resembling metachromatic or polyphosphate granules. Septation occurs by double ingrowth of the wall leading to fragmentation (type II; Williams et al., 1973). This may be associated with lamellar mesosomes up to 0.25 µm in diameter.

The sheath surrounding the spores of *Saccharopolyspora hirsuta* is 18–36 nm thick. It carries tufts of structureless hairs, triangular and 0.2–0.3 µm across at the base, which extend into apical filaments about 20 nm in diameter. The hairs are long, straight, or curved, and brittle (Figure 324). The morphology of the hairs is best seen on lengths of empty sheath (Figure 325) or by scanning electron microscopy (Figure 326). Spore walls are thickened uniformly to 50–60 nm, but their internal structure resembles that of hyphae, though they contain few vacuoles (Figure 327).

Two types of hyphae have been distinguished in thin sections of *Saccharopolyspora rectivirgula*, one having walls 19–25 nm thick and the other with walls 11–15 nm thick (Dorokhova et al., 1970). The cytoplasm in the thicker-walled cells is uniformly fine grained with a large nuclear zone extending the full-length of the cell. In thinner walled cells, the cytoplasm is less compact and homogeneous and the nuclear zone appears as small areas of low density. Mesosomes are less developed than in the thicker wall cells. Hyphae tend to autolyze during prolonged incubation at 55°C or at room temperature.

The spore chains of *Saccharopolyspora rectivirgula* are surrounded by a multilayered sheath, although this is less evident on spore chains formed on the substrate mycelium than on those produced on the aerial mycelium (Dorokhova et al., 1969; Williams et al., 1976). The spores are covered by a wall

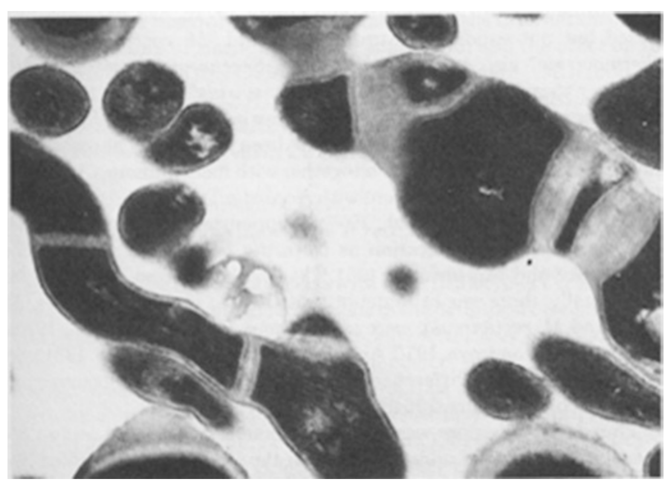

FIGURE 328. Sections of mycelium of *Saccharopolyspora rectivirgula* showing double septa in normal hyphae and irregular thickened septa in enlarged hyphae or aberrant spore chains (25,000×).

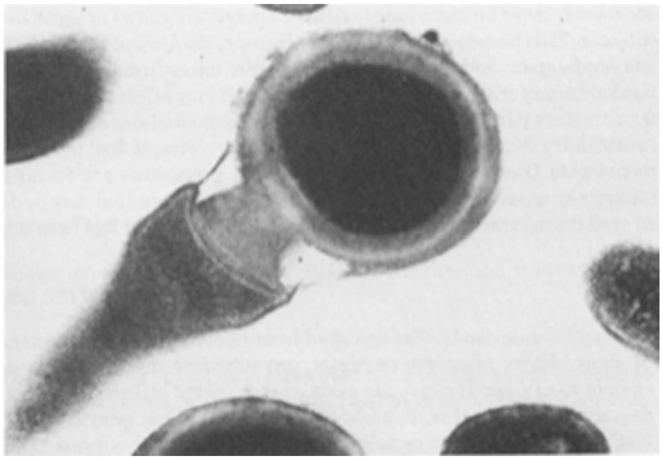

FIGURE 329. Longitudinal section through a developing spore of *Saccharopolyspora hirsuta* (40,000×).

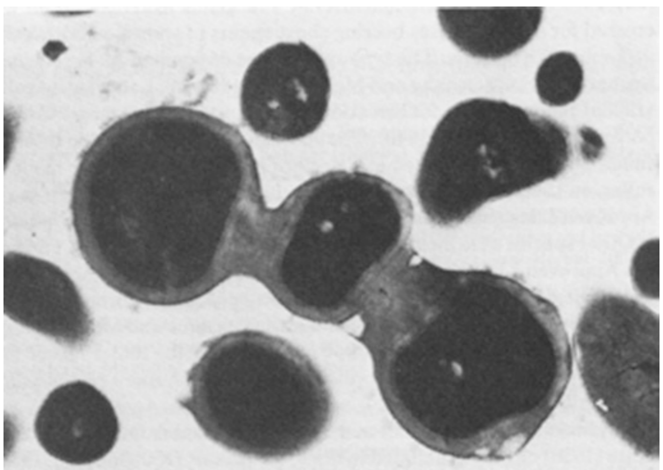

FIGURE 330. Longitudinal section through a developing spore of *Saccharopolyspora rectivirgula* showing interspore pads (25,000×).

70–100 nm thick in which two layers may be distinguished (Figure 328 and Figure 329), differing in thickness and electron density. Additional thickening of the cross-walls usually occurs giving characteristic interspore pads (Dorokhova et al., 1969) (Figure 330). These may sometimes be seen by light microscopy of stained preparations as conspicuous non-staining areas (Cross et al., 1968), but they may break down as the spore matures (Dorokhova et al., 1969). Plasmodesmata have been observed within the interspore pads. The protoplast is separated from the wall by a membrane and contains small, dark, densely packed ribosomes. Mesosomes are well developed and often adjoin the nuclear material. Although the spores are characteristically round or oval, spores of irregular shape are often seen in sections.

Colony morphology. Saccharopolysporae grow well on most standard media used to cultivate filamentous actinomycetes, such as Czapek's, glucose-asparagine (ISP medium 5), inorganic salts-starch (ISP medium 4), Sauton's, and V-8 vegetable juice agars. Colonies vary in size, in the extent of aerial hyphae production, and in aerial and substrate mycelia pigments. Those of *Saccharopolyspora hirsuta*, for instance, are thin,

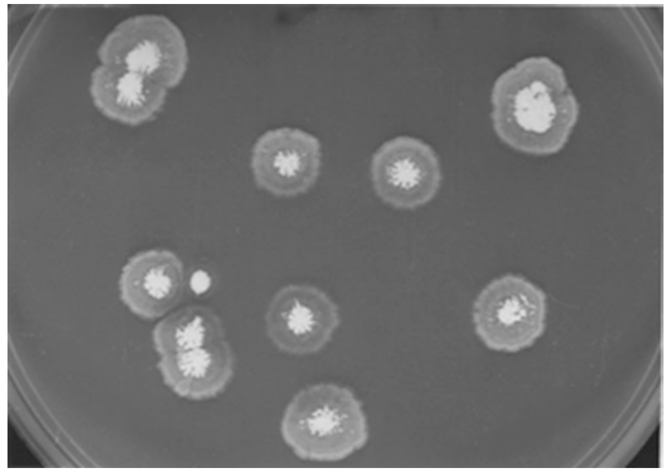

FIGURE 331. Colonies of *Saccharopolyspora hirsuta*. Half-strength nutrient agar, incubation 37°C (×1). (Reproduced with permission from Lacey and Goodfellow, 1975. J. Gen. Microbiol. *88*: 75–85.)

round or convex, wrinkled, and grow to about 1 cm in diameter in 7 d at 40°C, with a central area of white aerial mycelium on an almost colorless substrate mycelium (Lacey, 1975), as illustrated in Figure 331. In contrast, colonies of *Saccharopolyspora rectivirgula* grow to 5 mm in diameter in 7 d at 40–50°C; the substrate mycelium may be colorless, brown-yellow, or orange-yellow and the aerial mycelium may be white to light pink, though it is often sparse or absent (Korn-Wendisch et al., 1989; Lacey, 1989c). The aerial mycelium of *Saccharopolyspora gregorii* is also at best sparse (Goodfellow et al., 1989b), whereas macroscopically visible aerial hyphae have not been observed in *Saccharopolyspora taberi* (Labeda, 1987). *Saccharopolyspora flava* only produces aerial hyphae after prolonged incubation on oatmeal agar (Lu et al., 2001). Additional details on other species can be found in the species descriptions.

Chemotaxonomy. *Saccharopolyspora* species have a wall peptidoglycan which is characterized by the presence of *meso*-diaminopimelic acid, arabinose, and galactose (wall chemotype IV *sensu* Lechevalier and Lechevalier, 1970), an A1γ peptidoglycan (Schleifer and Kandler, 1972), and *N*-acetylated muramic acid (Duangmal et al., 2010). They have fatty acid profiles rich in iso- and anteiso-branched components in which $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso tend to predominate (Embley et al., 1987; Goodfellow et al., 1989b; Tang et al., 2009a, 2009b) and lack mycolic acids (Mertz and Yao, 1990; Minnikin et al., 1975; Pimentel-Elardo et al., 2008; Zhou et al., 1998), but typically contain major amounts of phosphatidylcholine, phosphatidylethanolamine, and phosphatidylmethylethanolamine (Embley et al., 1988b; Korn-Wendisch et al., 1989; Pimentel-Elardo et al., 2008) with a variable distribution of diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides (Li et al., 2009a; Yassin, 2009; Yuan et al., 2008) and, hence, have polar lipid pattern type III after Lechevalier et al. (1981, 1977b). A major glycolipid has been detected in *Saccharopolyspora erythraea*, *Saccharopolyspora hirsuta*, and *Saccharopolyspora rectivirgula* (Gamian et al., 1996). The predominant menaquinones are tetrahydrogenated with nine isoprene units [MK-9(H_4)] (Embley et al., 1988b; Korn-Wendisch et al., 1989; Tang et al., 2009a, 2009b), though smaller amounts

of MK-9(H_2, H_6, H_8) may be present (Alderson et al., 1985; Collins et al., 1977; Lu et al., 2001; Qin et al., 2008a). The type strain of *Saccharopolyspora thermophila* contains MK-9(H_6, H_8) as the predominant isoprenologs (Lu et al., 2001), though this apparently anomalous result may reflect the time when the culture was sampled as there is evidence that the menaquinone composition of *Amycolatopsis* and *Streptomyces* strains can be age-dependent (Saddler et al., 1986; Yassin et al., 1991). There is preliminary evidence that the esterase patterns of *Saccharopolyspora* strains may be species-specific (Korn-Wendisch et al., 1989).

Nutrition and growth conditions. In general, saccharopolysporae do not have any specific growth requirements and can grow on a diverse range of compounds as sole sources of carbon and nitrogen (Lacey and Goodfellow, 1975; Li et al., 2009a; Zhang et al., 2009). They grow well in media supplemented with salt, notably *Saccharopolyspora halophila* and *Saccharopolyspora qijiaojingensis*, which grow in the presence of 20% (w/v) NaCl (Tang et al., 2009a, 2009b). The type strain of *Saccharopolyspora cebuensis* has a strict requirement for salt which suggests that it is an obligate marine actinomycete (Pimentel-Elardo et al., 2008). Saccharopolysporae show a range of temperature requirements; some, such as *Saccharopolyspora hirsuta*, *Saccharopolyspora hordei*, *Saccharopolyspora rectivirgula*, and *Saccharopolyspora thermophila*, are moderate thermophiles (Goodfellow et al., 1989b; Lacey and Goodfellow, 1975; Lu et al., 2001). Most strains grow within the pH range 5.0–9.0 (Qin et al., 2008a; Tang et al., 2009b; Zhang et al., 2009).

Metabolism. Saccharopolysporae are aerobic, catalase-positive, chemo-organotrophic actinomycetes which have an oxidative metabolism. They degrade a broad range of organic substrates and use diverse compounds as sole carbon sources (Goodfellow et al., 1989b; Lacey and Goodfellow, 1975; Yuan et al., 2008). Isolates from fodder and other plant material typically degrade hypoxanthine, starch, Tweens, tyrosine, and xanthine, but not xylan (Goodfellow et al., 1989b; Lacey, 1989c).

Members of the genus are best known as a source of secondary metabolites, notably *Saccharopolyspora erythraea*, which is used for the industrial scale production of the clinically important macrolide antibiotic, erythromycin A, and *Saccharopolyspora spinosa*, the source of spinosyns A and D, glycosylated polyketide-derived macrolides which are commercially marketed as the insecticide spinosad (Hong et al., 2006, 2008; Huang et al., 2009). However, despite the commercial importance of these organisms, relatively little is known about their metabolic properties, apart from studies on erythromycin (Chen et al., 2008; Katz and Donadio, 1995; Reeves et al., 2006, 2007; Staunton and Weissman, 2001; Weissman et al., 2004) and spinosyn (Gaisser et al., 2001; Hong et al., 2008; Huang et al., 2009; Kim et al., 2007; Kirst et al., 1991, 1992; Waldron et al., 2001) biosynthesis and on host–vector systems developed for *Saccharopolyspora erythraea* (Gaisser et al., 2000). "*Saccharopolyspora pogona*" (Lewer et al., 2002) synthesizes pogonins (butylene-spinosyns), pericidal macrolides which are similar to the spinosyns produced by *Saccharopolyspora spinosa* (Hahn et al., 2006). Another taxon that does not have a validly published name, "*Saccharopolyspora aurantica*", forms a complex of pesticidal compounds designated CL307-24 (Etienne et al., 1993).

The erythromycins are broad-spectrum antibiotics active against Gram-stain-positive bacteria (Labeda, 1987; Staunton and Weissman, 2001). Erythromycin A, the most widely used and clinically effective member of the family, contains a characteristic 14-membered macrolide to which are attached two unusual deoxysugars, desosamine and mycarose (Chen et al., 2008). The entire gene cluster governing the biosynthesis of erythromycin A has been cloned and each open reading frame has been characterized by targeted gene inactivation. Erythromycins B and C, which are biologically less active and cause greater side effects, are intermediates in erythromycin A biosynthesis.

Spinosyns are unique macrolides with a tetracyclic core, which consists of a 12-membered macrocyclic lactone fused to a 5,6,5-*cis*-anti-*trans* tricyclic ring system, to which the deoxysugars forosamine and tri-*O*-methylated rhamnose are attached (Huang et al., 2009). The biosynthetic pathway of spinosyns have been determined, notably in studies based on precursor-labeling, identification of intermediate metabolites using blocked mutants, and by *in vitro* analysis of enzymes involved in spinosyn biosynthesis (Kirst et al., 1993). To date, more than 25 spinosyns have been isolated and identified from *Saccharopolyspora spinosa* (Crouse et al., 2001). The most abundant spinosyns from fermentation broths of this organism are spinosyn A (approx. 85% of spinosad) and spinosyn D (approx. 15% of spinosad). Spinosad kills susceptible insects by causing rapid excitation of the insect nervous system, probably through the interaction and binding of the δ-aminobutyric acid and nicotinacetylcholine receptor sites (Millar and Denholm, 2007).

Bioactive compounds are also produced by other *Saccharopolyspora* species. *Saccharopolyspora hirsuta* synthesizes a macrolide, nargenicin A (Ikeda et al., 1985), an aminoglycoside complex, apramycin and derivatives (Kamiya et al., 1983; O'Connor et al., 1976), and a cyclic polyketide, nodusmicin (Whaley et al., 1980). *Saccharopolyspora hirsuta* subsp. *kobensis* produces sporaricin and related aminoglycoside antibiotics (Deushi et al., 1979; Umezawa et al., 1987) and *Saccharopolyspora* sp. strain AC 3440 produces 4-deamino-4-hydroxyapromycin (Awata et al., 1983). *Saccharopolyspora erythraea* is a rich source of bioactive compounds other than erythromycin, including erythronolide B (Martin and Rosenbrook, 1967), an *N*-acetylmuramidase (Morita et al., 1978), a trypsin-like protease (Yoshida et al., 1971), and a rennin-like enzyme (Sternberg, 1976).

The genome of *Saccharopolyspora erythraea* NRRL 2338^T has been sequenced (Oliynyk et al., 2007), a development which is promoting interest in the metabolism and biotechnological exploitation of this and related actinobacteria (Katz and Khosla, 2007; Peano et al., 2007). The genome of this organism shows considerable divergence from those of streptomycetes in gene organization and function thereby confirming previous taxonomic insights (Labeda, 1987). Oliynyk and his colleagues reported that the *Saccharopolyspora erythraea* genome contained at least 25 gene clusters for the production of known and predicted secondary metabolites, at least 72 genes predicted to confer resistance to a range of common antibiotic classes and many sets of duplicated genes to support the saprophytic way of life of the organism. The latter included genes involved in defense and stress responses, in ensuring or preserving correct protein folding, and those encoding a wide range of degradative enzymes, including seven chitinases and multiple glucanases and proteinases. The genome sequence of *Saccharopolyspora erythraea* sets the stage for understanding the biology of this organism both in nature and in the fermentation process and for explaining

the higher levels of erythromycin production in industrially significant strains (Katz and Khosla, 2007).

Genetics. Most studies have been directed towards mapping and cloning of the erythromycin biosynthesis and resistance genes of *Saccharopolyspora erythraea* (Baltz et al., 1986; Bibb et al., 1986; Stanzak et al., 1986; Tuan et al., 1986; Vanden Boom, 2000; Weber et al., 1985) and on the cloning and analysis of the *Saccharopolyspora spinosa* spinosad biosynthetic gene cluster (Hong et al., 2008; Matsushima and Baltz, 1994; Matsushima et al., 1994; Waldron et al., 2001). The erythromycin genes are located on the chromosome, together with resistance and regulatory elements (Oliynyk et al., 2007; Stanzak et al., 1986; Weber et al., 1985). Most of the *Saccharopolyspora spinosa* genes involved in spinosyn biosynthesis are present in a 74 kb cluster with characterization studies suggesting that spinosyns are synthesized by mechanisms similar to those used to assemble complex macrolides from primary metabolic precursors as in other actinobacteria (Waldron et al., 2001). These workers noted that several unusual genes in the spinosyn gene cluster might encode enzymes which generate the tetracyclic polyketide aglycone nucleus, the most striking structural feature of spinosyns.

Integrated and conjugative elements (AICEs) have been detected in *Saccharopolyspora erythraea* (Brown et al., 1988, Brown et al., 1994; te Poele et al., 2008). te Poele and her colleagues found two novel putative AICEs in the *Saccharopolyspora erythraea* genome, one of which (PSE102) encoded a putative aminoglycoside phosphotransferase which may confer antibiotic resistance to the host. They also found that the AICEs of *Saccharopolyspora erythraea*, *Amycolatopsis mediterranei*, and *Amycolatopsis methanolica* have a highly conserved structural organization which consists of four functional modules (conjugative transfer, excision/integration, regulation, and replication). Identification and characterization of mobile genetic elements is important for the manipulation of commercially significant *Saccharopolyspora* strains.

The genes responsible for the biosynthesis of erythromycin were cloned into but not well expressed in "*Streptomyces lividans*" (Stanzak et al., 1986; Thompson et al., 1982), a problem reflecting the phylogenetic gulf between *Saccharopolyspora* and *Streptomyces* strains (Embley et al., 1988a) and, thereby, emphasizing the need to develop cloning systems based on indigenous *Saccharopolyspora* vectors (Gayer-Herkert et al., 1989; Katz et al., 1988). There is evidence that *Streptomyces* phages are unstable in *Saccharopolyspora* strains (Gayer-Herkert et al., 1989; Yamamoto et al., 1986). Plasmids have been detected in the type strain of *Saccharopolyspora erythraea* (Brown et al., 1986; Chiang et al., 1985) and methods for the transformation of *Saccharopolyspora erythraea* (Yamamoto et al., 1986) and *Saccharopolyspora rectivirgula* (Gayer-Herkert et al., 1989) have been described.

The *Saccharopolyspora spinosa* spinosad biosynthetic gene cluster has been cloned, analysed, and shown to contain five large open reading frames which encode a multifunctional type 1 polyketide synthase (Waldron et al., 2001). The enzymes involved in D-forosamine [(4-dimethylamino)-2,3,4,6-tetradeoxy-β-D-*threo*-hexopyranose] biosynthesis in the spinosyn pathway have been cloned and expressed heterologically and the corresponding proteins have been purified and their activities examined *in vitro,* developments which have elucidated the mechanisms for the synthesis of this highly deoxygenated sugar (Hong et al., 2008). Indeed, these studies have provided the basis for future work on the biosynthesis of 2,3,6-trideoxy- and 2,3,4,6-tetradeoxyhexoses present in many bioactive natural products.

The sequenced chromosome of the type strain of *Saccharopolyspora erythraea* (8.2 kb) is circular like those of *Amycolatopsis mediterranei*, *Corynebacterium diphtheriae*, and *Mycobacterium tuberculosis*, but unlike the linear chromosomes of "*Streptomyces coelicolor*" A(3)2 and *Streptomyces avermitilis* MA-4680 (Oliynyk et al., 2007; Peano et al., 2007; Zhao et al., 2010). Approximately, half of the chromosome, which contains more than 7200 genes, consists of a core region which includes most of the genes required for primary metabolism, cell division, information transfer, and sporulation (Katz and Khosla, 2007). Erythromycin biosynthesis is encoded in the core region, which suggests that this natural product has been integral to the evolutionary success of this organism. The remaining half of the chromosome contains most of the remaining gene clusters involved in secondary metabolism, including genes for the biosynthesis of unknown polyketides, ribosomal peptides, and terpenoids.

It is clear that *Saccharopolyspora erythraea* has a remarkable capacity for the production of secondary metabolites, a trait which seems likely to confer substantial advantages to the organism in the soil milieu. Indeed, it has been suggested that the ability to deploy a differential chemical arsenal may be a general evolutionary strategy used by actinobacteria which grow as filamentous mycelia in highly competitive environments (Challis and Hopwood, 2003; Jenke-Kodama et al., 2006). A detailed understanding of the transcriptional organization of the *Saccharopolyspora erythraea* chromosome has been attained by using GeneChip DNA microarrays derived from the complete gene sequence of this organism (Peano et al., 2007). The use of the *Saccharopolyspora erythraea* DNA microarray improved the specificity and sensitivity of gene expression analysis, allowing a global and, at the same time, detailed understanding of how *Saccharopolyspora erythraea* genes are modulated. The results confirmed that the erythromycin gene cluster is upregulated during the initial growth phase of the organism, and identified six additional clusters – for non-ribosomal peptides and terpenes – that are regulated in later growth phases.

Bacteriophages. Until recently, considerable interest was shown in *Saccharopolyspora* phages both as cloning vectors (Katz et al., 1988; Schneider and Kutzner, 1989) and taxonomic markers (Korn-Wendisch et al., 1989; Labeda, 1987; Prauser and Momirova, 1970). Most attention was focused on phages isolated from *Saccharopolyspora erythraea* and *Saccharopolyspora rectivirgula* (Donadio et al., 1986; Grund and Hutchinson, 1987; Katz et al., 1988; Kempf et al., 1987; Schneider et al., 1987) using methods similar to those developed for *Streptomyces* species (Hopwood et al., 1985; Lanning and Williams, 1982), albeit with minor modifications and the use of appropriate baiting and indicator strains (Greiner-Mai et al., 1987; Grund and Hutchinson, 1987; Kurup and Heinzen, 1978).

Some phages isolated from *Saccharopolyspora erythraea* were found to infect and multiply in *Saccharopolyspora rectivirgula* and *vice versa* (Korn-Wendisch et al., 1989; Smorawinska et al., 1988). Some *Saccharopolyspora erythraea* phages have been shown to infect *Saccharopolyspora hirsuta* and *Saccharopolyspora taberi* (Grund and Hutchinson, 1987; Korn-Wendisch et al., 1989). Phage life cycle and plaque morphology are also host-dependent, whereas phages lysogenic for one host may lyse another (Brzezinski et al., 1986; Kempf et al., 1987; Schneider and Kutzner, 1989).

Saccharopolyspora phages have a tail of variable length attached to an icosahedron capsid which encloses a double-stranded genome with *cos* termini present in some strains (Grund and Hutchinson, 1987; Katz et al., 1988; Kurup and Heinzen, 1978; Schneider et al., 1987; Schneider and Kutzner, 1989). The central regions of representative phages from *Saccharopolyspora erythraea* (Brzezinski et al., 1986) and *Saccharopolyspora rectivirgula* (Schneider et al., 1987) are variable due to the deletion or insertion of large gene fragments (Brzezinski et al., 1986; Schneider et al., 1987; Schneider and Kutzner, 1989; Smorawinska et al., 1988). Hybridization studies (Schneider and Kutzner, 1989) have shown that the same or related elements occur in the genomes of *Saccharopolyspora rectivirgula* phages representing different compatability groups and in a phage isolated from *Saccharopolyspora erythraea* (Brzezinski et al., 1986).

Antibiotic sensitivity patterns. In general, saccharopolysporae are resistant to a broad range of antibiotics though studies have been limited to species such as *Saccharopolyspora antimicrobica*, *Saccharopolyspora gregorii*, *Saccharopolyspora hirsuta*, *Saccharopolyspora hordei*, and *Saccharopolyspora spinosa*. The antibiotic sensitivity profiles of these and other *Saccharopolyspora* species are given in the species descriptions.

Pathogenicity. Saccharopolysporae are not known to cause infections though *Saccharopolyspora rectivirgula* is the chief agent of the extrinsic allergic alveolitis condition known as farmer's lung (Campbell, 1932; Pepys et al., 1963). This disease, which occurs widely in China, Europe, Japan, and the USA, is caused by the inhalation of large numbers of spores released when moldy substrates are disturbed in the presence of sensitized individuals (Lacey, 1981). In western Scotland and the Orkneys, it has been reported to affect up to 8.6% of farm workers (Grant et al., 1972), whereas in the US, 8.4% of Wisconsin dairy farmers had precipitins to actinobacteria, nearly 90% of them to *Saccharopolyspora rectivirgula* (Roberts et al., 1976). Farmer's lung is normally a chronic rather than an acute disease, although fatalities have been recorded (Lacey, 1988). *Saccharopolyspora hordei* spores are also found in high numbers in grain stores and may be involved as an agent of extrinsic allergic alveolitis (Lacey and Crook, 1988). Respiratory diseases resembling farmer's lung have been reported in cattle and horses exposed to moldy hay (Lacey, 1988; Pirie et al., 1971) and an acute outbreak resulting in several fatalities has been reported in Canadian cattle (Wilkie, 1978).

The criteria used for the diagnosis of extrinsic allergic alveolitis, including farmer's lung, have been considered by Lacey (1988). Antigens from *Saccharopolyspora rectivirgula* have been purified, which can be used for the detection of circulating antibodies in the sera of patients (Brummund et al., 1988; Mäntyjärvi and Kurup, 1988). An enzyme-linked immunosorbent assay has also been developed for this purpose (Ramasamy et al., 1987).

Antigenicity. The antigenicity of *Saccharopolyspora rectivirgula* has received a lot of attention since the organism, first known as *Thermopolyspora polyspora*, then as *Micropolyspora faeni* and *Faenia rectivirgula*, was implicated in farmer's lung (Pepys et al., 1963). Initially, three precipitin arcs were recognized in gel diffusion and immunoelectrophoresis tests using extracts of *Saccharopolyspora rectivirgula* and sera from farmer's lung patients. Using gel filtration, adsorption on DEAE columns and elution with crossed immunoelectrophoresis and immunodiffusion, the precipitins have been resolved into up to 75 individual antigenic components, as outlined by Lacey (1989a).

Ecology. Members of the genus *Saccharopolyspora* have been isolated from a broad range of habitats, notably plant material which has been stored and allowed to decay (Lacey, 1971, 1974, 1978). *Saccharopolyspora rectivirgula* is common in spontaneously heating vegetable material. It was first isolated from moldy hay which had been baled containing more than 35% water content and heated to 50–65°C (Gregory et al., 1963). Subsequently, it has been found in cereal grain, cotton bales, mushroom compost, straw, sugar corn bagasse, and the air over pastures (Lacey, 1978). Heating of the substrate is initiated by plant cells and mesophilic bacteria and fungi. The organism begins to grow at 30 to 35°C, but larger numbers are found in hays that heat to around 60°C after baling at about 39% water content. The change in pH from 5.5–6.0 to 7.0–8.0 caused by fungal proteolysis probably favors actinobacterial colonization though *Saccharopolyspora rectivirgula* can sometimes grow in hay without pretreatment (Gregory et al., 1963). It can survive in moist grains stored anaerobically in silos and its spores can withstand up to 20 min at 70°C.

Other species isolated from plant material include *Saccharopolyspora gregorii*, *Saccharopolyspora hirsuta*, and *Saccharopolyspora hordei*. *Saccharopolyspora hirsuta* is known mostly from moldy sugar cane bagasse that has heated spontaneously during storage. It was found in 12% of samples originating in India, Jamaica, Puerto Rico, and Trinidad (Lacey, 1974). Strains of *Saccharopolyspora hordei* are common in stored barley and hay and are found less frequently in sugar cane bagasse. This organism, together with *Saccharopolyspora rectivirgula*, was present in 15% of freshly harvested grain samples, but not in grass used to seal moist barley silos (Lacey, 1971). However, after storage they occurred in 33% of grass and straw samples and in 57% and 32% of grain samples in two seasons. *Saccharopolyspora rectivirgula* has been isolated from a range of vegetable material collected from different sites in the Nigerian states of Anambra and Enugu (Unaogu et al., 1994). *Saccharopolyspora gregorii* has been infrequently isolated from barley, stored hay, and straw (Goodfellow et al., 1989b). Saccharopolysporae may also be present on lichens (Gonzalez et al., 2005).

Developments in the systematics of *Saccharopolyspora* provide good grounds for the recognition of novel species isolated from diverse man-made and natural habitats. Novel species from terrestrial habitats include *Saccharopolyspora flava* and *Saccharopolyspora thermophila* from garden soil (Lu et al., 2001), *Saccharopolyspora phatthalungensis* from the rhizosphere of *Hevea brasiliensis* (Duangmal et al., 2010), *Saccharopolyspora shandongensis* from wheat field soil (Zhang et al., 2008b), *Saccharopolyspora tripterygii* from a surface-sterilized stem sample from *Trypterygium hypoglaucum* (Li et al., 2009a), and "*Saccharopolyspora endophytica*" from a root of *Mytenus austroyunnanensis* (Qin et al., 2008a). In addition, *Saccharopolyspora halophila* and *Saccharopolyspora qijiaojingensis* were isolated from saline salt lakes (Tang et al., 2009a, 2009b), *Saccharopolyspora cebuensis* was from a sponge (Pimentel-Elardo et al., 2008), *Saccharopolyspora rosea* was from a patient with bronchial carcinoma (Yassin, 2009), and *Saccharopolyspora spinosa* was from soil collected from a sugar mill rum still (Mertz and Yao, 1990).

Isolation procedures

The isolation of *Saccharopolyspora* from airborne dust, grain, fodder, and other vegetable material is best achieved by using

an Andersen sampler (Andersen, 1958) to examine spore clouds generated using a wind tunnel or sedimentation chamber (Gregory and Lacey, 1963; Lacey and Dutkiewicz, 1976a, 1976b). Sedimentation of spore clouds should be allowed to proceed for 10–30 min in order to allow larger particles to settle as the lighter actinomycete spores remain airborne. The Andersen sampler should be loaded with appropriate isolation media supplemented with cycloheximide (50 μg/ml) to inhibit the growth of fungi (Cross et al., 1968).

Colonies of *Saccharopolyspora hirsuta* were first isolated from airborne sugar cane bagasse dust (Lacey, 1974) using a wind tunnel and an Andersen sampler (Lacey and Goodfellow, 1975). The medium, half-strength nutrient agar supplemented with cycloheximide, was incubated at 40°C following inoculation. The resultant colonies were colorless to pale brown, thin, and raised or convex and carried small tufts of white aerial mycelia in the centers. The same procedure was used to isolate *Saccharopolyspora gregorii* and *Saccharopolyspora hordei* from cereal grain and hay (Goodfellow et al., 1989b; Lacey, 1971). Isolation of *Saccharopolyspora gregorii* is enhanced at 30°C.

Dilution and direct plating procedures have been used to isolate *Saccharopolyspora rectivirgula*, but enumeration in hay and other vegetable matter is best achieved by using an Andersen sampler to impact airborne spores onto appropriate media. A range of media can be used, including half-strength nutrient agar (Lacey, 1971, 1974), half-strength tryptone soy agar supplemented with casein hydrolysates (Lacey, 1989a), R8 agar (Amner et al., 1989), and starch-casein-arginine agar (Iwasaki et al., 1979). Hippurate has been used as a selective carbon source for the isolation of *Saccharopolyspora rectivirgula* (Mattinson-Rose, 1986). This investigator used the membrane-filter method of Hirsch and Christensen (1983) to isolate *Saccharopolyspora hirsuta* from dilutions of substrate suspensions; only mycelial actinomycetes can grow through the pores in membrane filters and thereby reach and grow on the surface of isolation media.

Small numbers of taxonomically diverse saccharopolysporae have been isolated from aquatic and terrestrial habitats by plating suspensions of substrates onto non-selective media, as exemplified by the isolation of *Saccharopolyspora antimicrobica* on yeast extract-malt extract agar (Yuan et al., 2008) and *Saccharopolyspora flava* on oatmeal agar (Lu et al., 2001). Additional strains have been isolated using more selective, but nevertheless empirical procedures, as illustrated by the isolation of *Saccharopolyspora halophila* on cellulose-casein multi-salts agar (Tang et al., 2009a) and *Saccharopolyspora phatthalungensis* on starch-casein agar supplemented with ketokamazole and nalidixic acid (Duangmal et al., 2010). In general, inoculated plates were incubated at 28°C for between 1 and 4 weeks.

Maintenance procedures

Working cultures of *Saccharopolyspora* strains can be maintained using refrigerated (4°C) agar slopes on media such as glucose-yeast extract agar (Gordon and Mihm, 1962), V8 vegetable juice agar (Corbaz et al., 1963), and yeast extract-malt extract agar (ISP medium 2; Shirling and Gottlieb, 1966). Similarly, halophilic strains can be maintained on inorganic salts-starch agar (ISP medium 4; Shirling and Gottlieb, 1966). Longer term preservation of strains is best achieved as frozen suspensions of mycelia and spores at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using standard lyophilization techniques.

Differentiation of the genus *Saccharopolyspora* from other genera

Saccharopolyspora strains can be distinguished from members of other genera classified in the family *Pseudonocardiaceae* by using a combination of chemical and morphological markers and by comparative 16S rRNA gene sequence studies (see the family *Pseudonocardiaceae*, above). It can be separated from other genera in the family on the basis of PAGE and sequence analysis of ribosomal AT-L30 proteins (Ochi, 1995; Ochi and Yoshida, 1991) and by the use of a genus-specific primer (Morón et al., 1999).

Taxonomic comments

The genus *Saccharopolyspora* was proposed by Lacey and Goodfellow (1975) to encompass actinobacteria from sugar cane bagasse that produced aerial mycelia with bead-like chains of spores enclosed in a characteristic hairy sheath. Subsequently, Labeda (1987) transferred the type species of *Streptomyces erythraeus* to the genus *Saccharopolyspora* as *Saccharopolyspora erythraea* because its cell walls contained *meso*-diaminopimelic acid, arabinose, and galactose. He also proposed that "*Nocardia taberi*" be reclassified as *Saccharopolyspora hirsuta* subsp. *taberi*, an organism later given species status as *Saccharopolyspora taberi* (Korn-Wendisch et al., 1989). Another taxon, "*Saccharopolyspora hirsuta* subsp. *kobensis*" (Iwasaki et al., 1979) was formally recognized by these investigators. Two other taxa, "*Saccharopolyspora aurantiaca*" and "*Saccharopolyspora hirsuta* subsp. *kunmingensis*" were described for strains isolated from soil taken from a rice field (Jiang and Xu, 1986). Three other species, *Saccharopolyspora gregorii*, *Saccharopolyspora hordei*, and *Saccharopolyspora spinosa*, were early additions to the genus (Goodfellow et al., 1989b; Mertz and Yao, 1990).

There have been numerous twists and turns in the classification and nomenclature of *Saccharopolyspora rectivirgula*, an organism designated *Faenia rectivirgula* in the last edition of *Bergey's Manual of Systematic Bacteriology* (Lacey, 1989a). The name *Faenia rectivirgula* was proposed by Kurup and Agre (1983) for the thermophilic actinobacterium *Micropolyspora faeni* (Cross et al., 1968) which had been previously named "*Thermopolyspora polyspora*" (Corbaz et al., 1963) and "*Thermopolyspora rectivirgula*" (Krasil'nikov and Agre, 1964). The genus name *Micropolyspora* lost its standing in nomenclature when its type strain, *Micropolyspora brevicatena*, was reclassified as *Nocardia brevicatena* (Goodfellow and Pirouz, 1982). The subsequent reclassification of *Faenia rectivirgula* as *Saccharopolyspora rectivirgula* (Korn-Wendisch et al., 1989) was supported by a wealth of taxonomic information, including data derived from chemotaxonomic (Collins et al., 1977; Embley et al., 1988b; Kroppenstedt, 1985; Mordarskaia et al., 1973), phage host range (Schneider and Kutzner, 1989; Smorawinska et al., 1988), and 16S rRNA gene sequencing (Bowen et al., 1989; Embley et al., 1988a, 1988c) studies. The name of the mesophilic species "*Faenia rectivirgula*", proposed by Okazaki et al. (1987), has not been validly published.

The genus *Saccharopolyspora* currently contains 20 species with validly published names, most of which have been delineated using a broad range of genotypic and phenotypic features, in some instances including DNA–DNA relatedness data

(Li et al., 2009a; Qin et al., 2008a; Yuan et al., 2008; Zhang et al., 2008b, 2009). However, despite the recent rise in the number of *Saccharopolyspora* species, mainly based on the description of single isolates, there is evidence that the genus is underspeciated (Goodfellow et al., 1989b).

Differentiation of the species of the genus *Saccharopolyspora*

Saccharopolyspora species can be distinguished by using a range of phenotypic markers (Table 255), though results need to be interpreted with care as a common set of tests are not yet available for the delineation of all species and because many of the latter are based on the description of single isolates. In practice, closely related *Saccharopolyspora* species are delineated using a combination of 16S rRNA gene sequence, DNA–DNA relatedness, and phenotypic data (Duangmal et al., 2010; Qin et al., 2008a). Some *Saccharopolyspora* species have been distinguished by differences in quantitative fatty acid composition (Embley et al., 1988b; Mertz and Yao, 1990) and on the basis of esterase patterns, plasmid profiles, and phage host range studies (Korn-Wendisch et al., 1989; Schneider and Kutzner, 1989).

List of species of the genus *Saccharopolyspora*

1. **Saccharopolyspora hirsuta** Lacey and Goodfellow 1975, 78[VP]

hir.su′ta. L. fem. adj. *hirsuta* hairy, rough, shaggy, bristly, referring to the hairy spore chains produced by the organism.

Forms branched, substrate hyphae (0.4–0.6 μm diameter) which tend to fragment into rod-shaped elements towards the edges and in older parts of colonies. Aerial hyphae (0.5–0.7 μm diameter) differentiate into bead-like spores which tend to be separated by short lengths of apparently "empty" hyphae. Looped or loosely spiral chains of spores are produced, though long straight chains of spores are sometimes formed between tufts of aerial hyphae. Spores are round to oval (0.7–1.3 × 0.5–0.7 μm) and are covered by a sheath bearing tufts of long straight or curved hairs. Thin, raised or convex, and usually slightly wrinkled colonies are formed in 7 d at 40°C. Sparse white aerial hyphae are produced in tufts at the center of colonies. The substrate mycelium is colorless to cartridge buff and usually gelatinous or mucoid. Good growth occurs on V-8 vegetable juice and yeast extract-malt extract (ISP medium 2) agars; a yellow diffusible pigment is formed on the latter. Grows on agar media between 25 and 50°C, with an optimal temperature of about 37 to 40°C; does not grow at 10°C. Aerial hyphae are only formed at the optimal temperature.

Degrades adenine, but not xylan. Adonitol, cellobiose, erythritol, glycerol, inositol, lactose, methyl α-D-glucoside, methyl β-D-glucoside, sorbitol, and trehalose are used as sole carbon sources, but not arabinose, melezitose, or salicin (all at 1%, w/v). Similarly, acetate, benzoate, butyrate, citrate, fumarate, H-malate, succinate, and sebacate acid are used as sole carbon sources, but not adipate or tartrate (all at 0.1%, w/v).

Resistant (filter paper discs soaked in μg/ml antibiotics) to erythromycin (50), gentamicin (100), kanamycin (10), streptomycin (100), neomycin (50), tobramycin (100), and rifampin (50), but susceptible to dapsone (500) and septrin (500). Sensitive to lysozyme. Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of iso- and anteiso-branched chain components. The predominant menaquinone is MK-9(H_4).

Source: isolated from moldy sugarcane bagasse spontaneously heated during storage.

DNA G+C content (mol%): not determined.

Type strain: ATCC 27875, CBS 420.74, DSM 43463, IFO (now NBRC) 13919, JCM 3170, NCIB 11079, NRRL B-5792.

Sequence accession no. (16S rRNA gene): U93341.

Taxonomic comments: subsequently, this species has been divided into subspecies.

1a. **Saccharopolyspora hirsuta subsp. hirsuta** Lacey and Goodfellow 1975, 78[VP]

Description is as for the species.

Additional comments: this subspecies was automatically created by the valid publication of *Saccharopolyspora hirsuta* subsp. *taberi* Labeda (1987) (Howey et al., 1990), a taxon subsequently raised to species status (Korn-Wendisch et al., 1989).

1b. **Saccharopolyspora hirsuta subsp. kobensis** (*ex* Iwasaki, Itoh and Mori 1979) Lacey 1989b, 496[VP] (Effective publication: Lacey 1989c, 2385.) (*Saccharopolyspora hirsuta* subsp. *kobensis* Iwasaki, Itoh and Mori 1979, 185)

ko.ben′sis. N.L. fem. adj. *kobensis* belonging to Kobe, a city in Japan where the organism was isolated.

Differs from *Saccharopolyspora hirsuta* subsp. *hirsuta* in having a yellow to pink substrate mycelium and a yellow to red soluble pigment, in reducing nitrate to nitrite, and by using inositol, rhamnose, sorbitol, and xylose. Source of the antibiotic sporacin.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: ATCC 20501, FERM-P 3912, NBRC 15151, JCM 9109, KC 6606.

Sequence accession no. (16S rRNA gene): DQ381814.

Additional comments: a revised name (Lacey, 1989b), cited in Validation List 31.

2. **Saccharopolyspora antimicrobica** Yuan, Zhang, Guan, Wei, Li, Yu, Li and Zhang 2008, 1184[VP]

an.ti.mi.cro′bi.ca. Gr. prep. *anti* against; N.L. n. *microbium* microbe; L. adj. suff. *-cus -a -um* suffix used with various meanings; N.L. fem. adj. *antimicrobica* antimicrobial.

Forms extensively branched, white, buff to pink substrate mycelia that later fragment into rod-shaped elements. Aerial hyphae differentiate into long straight chains of rough-surfaced spores. Grows well on glycerol-asparagine (ISP medium 5), inorganic salts-starch (ISP medium 4), oatmeal (ISP

medium 3), and yeast extract-malt extract (ISP medium 2) agars. White aerial hyphae are produced on ISP 2 agar. Diffusible pigments, buff, pink to brown, are produced on some agar media. Grows in the presence of 0–7% (w/v) NaCl. Temperature and pH ranges for growth are 20–45°C and pH 6.0–8.5, respectively. Optimal temperature and pH for growth are 28–37°C and pH 7.0–7.5, respectively.

Gelatin and xylan are degraded, but not cellulose, chitin, or elastin. Milk is coagulated and peptonized, but does not produce H_2S. Positive for acid phosphatase, alkaline phosphatase, β-galactosidase, α-glucosaccharase, β-glucosaccharase, and *N*-acetylglucosaminidase. Adonitol, cellobiose, dutcitol, inositol, melezitose, melibiose, D-ribose, salicin, sorbitol, turanose, acetate, citrate, malonate, phenylalanine, glyconate, glucosamine, and tartrate are used as sole carbon sources, but not erythritol, methyl α-D-glucoside, or trehalose.

Resistant (μg/ml) to amikacin (30), ampicillin (10), aztreonam (30), cefotaxime (30), ceftazidime (30), chloromycetin (30), erythromycin (15), furadantin (300), gentamicin (10), oxacillin (1), penicillin G (10 U), streptomycin (10), and tobramycin (10). Inhibited by lysozyme. Shows antimicrobial activity against *Escherichia coli* and *Staphylococcus aureus*. Additional phenotypic features are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{17:0}$ anteiso. The predominant menaquinone is MK-9(H_4) and the major phospholipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol.

Source: isolated from soil.

DNA G+C content (mol%): 69.3 (T_m).

Type strain: I05-00074, CCM 7463, DSM 45119, KCTC 19303.

Sequence accession no. (16S rRNA gene): EF693956.

3. **Saccharopolyspora cebuensis** Pimentel-Elardo, Tiro, Grozdanov and Hentschel 2008, 631[VP]

ce.bu.en′sis. N.L. fem. adj. *cebuensis* pertaining to the province of Cebu in the Philippines where the type strain was collected.

Forms extensively branched white substrate hyphae which fragment into rod-shaped elements. Aerial hyphae bear short chains of round to oval spores with smooth surfaces. Brown diffusible pigment is observed. Grows at 15–37°C on yeast extract-malt extract (ISP medium 2) or M1 agars which contain 2.5–12.5% (w/v) NaCl or 25–100% artificial seawater. Does not grow anaerobically.

Positive for acid phosphatase, alkaline phosphatase, esterase (C4), esterase lipase (C8), α-glucosidase, leucine arylamidase, lipase (C14), α-mannosidase, naphthol-A-BI-phosphohydratase, *N*-acetyl-β-glucosaminidase, and valine arylamidase (API ZYM tests). Catalase-positive and oxidase-negative.

Amygdalin, D-arabinose, arabitol, cellobiose, dulcitol, erythritol, esculin, fucose, gentiobiose, glycerol, glycogen, inulin, *N*-acetylglucosamine, potassium gluconate, ribose, starch, and trehalose are used as sole carbon sources. Additional phenotypic features are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of iso-, anteiso-, and 10-methyl-branched fatty acids. The predominant menaquinone is MK-9(H_4) and the major polar lipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylmethylethanolamine.

Source: isolated from a marine sponge (*Haliclona* sp.).

DNA G+C content (mol%): 72.6 (HPLC).

Type strain: DSM 45019, CIP 109355, SPE 10-1.

Sequence accession no. (16S rRNA gene): EF030715.

4. **Saccharopolyspora erythraea** (Waksman 1923) Labeda 1987, 21[VP] [*Actinomyces erythreus* Waksman 1923, 370; *Streptomyces erythreus* (Waksman 1923) Waksman and Henrici 1948, 938]

e.ry.thra′e.a. L. fem. adj. *erythraea* reddish, referring to colony color.

Forms an extensively branched substrate mycelium. Spore chains are usually short so that imperfect spirals and short to flexuous chains are common. Spore surfaces are spiny. Substrate mycelium ranges from pale orangish yellow to reddish brown, depending on the medium. Pale pink to moderately brownish gray aerial hyphae are formed on many media, including glycerol-asparagine agar (ISP medium 5). White aerial mycelia are seen. A faint yellow to pinkish orangish brown soluble pigment is produced on most media. Melanin pigments are not produced. Grows between 20 and 42°C.

Degrades gelatin, but does not produce phosphatase or hydrolyze allantoin. Acid is produced from adonitol, arabinose, cellobiose, dextrin, erythritol, fructose, galactose, glucose, glycerol, inositol, maltose, mannitol, mannose, melezitose, melibiose, raffinose, rhamnose, salicin, sucrose, and xylose, but not from dutcitol, lactose, methyl α-D-glucoside, methyl β-D-xyloside, or sorbitol. Acetate, citrate, lactate, malate, propionate, pyruvate, and succinate are used as sole carbon sources, but not benzoate, mucate, oxalate, or tartrate. Many strains produce erythromycins A or B. Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the predominant principal diamino acid. The predominant menaquinone is MK-9(H_4).

Source: isolated from soil.

DNA G+C content (mol%): 76.9 (T_m).

Type strain: ATCC 11635, DSM 40517, ISP 5517, NRRL 2338.

Sequence accession no. (16S rRNA gene): X53198.

Additional comments: Saccharopolyspora erythraea (Waksman 1923) Labeda 1987 comb. nov. was initially described as *Saccharopolyspora erythraea* sp. nov. However, since *Saccharopolyspora erythraea* Labeda 1987 contains the type strain of *Streptomyces erythraeus* (Waksman 1923) Waksman and Henrici 1948 (Approved Lists, Skerman et al., 1980), the taxon has to be considered as a new combination, *Saccharopolyspora erythraea* (Waksman 1923) Labeda 1987.

5. **Saccharopolyspora flava** Lu, Liu, Wang, Zhang, Qi and Goodfellow 2001, 322[VP]

fla′va. L. fem. adj. *flava* yellow, referring to the color of the substrate mycelium.

Forms an extensively branched, yellow substrate mycelium which fragments into rod-shaped elements after 3–4 d at 28°C. Aerial hyphae are produced after prolonged cultivation on oatmeal agar. The aerial mycelium carries abundant straight chains of 3–5 smooth surfaced spores (0.4–0.5 × 0.6 µm). The organism grows well on glucose-asparagine, modified Sauton's, and yeast extract-malt extract (ISP medium 2) agars. Does not produce diffusible pigments. Grows between 28 and 37°C. Weak growth occurs in the presence of 7% (w/v) NaCl.

Cellulose and xylan are degraded, but not guanine. Utilizes adonitol, cellobiose, erythritol, glycerol, inositol, methyl α-D-glucoside, salicin, sorbitol, acetate, adipate, benzoate, butyrate, citrate, fumarate, H-malate, propionate, pyruvate, and succinate as sole carbon sources, but not melezitose, sebacic acid, or tartrate.

Sensitive (discs soaked in 100 µg/ml antibiotic) to gentamicin, streptomycin, and rifampin. Sensitive to lysozyme. Additional phenotypic features are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. The predominant menaquinone is MK-9(H_4) and the polar lipid pattern includes phosphatidylcholine.

Source: isolated from garden soil.

DNA G+C content (mol%): 67 (T_m).

Type strain: 07, AS4.1520, DSM 44771, NBRC 16345, JCM 10665.

Sequence accession no. (16S rRNA gene): AF154128.

6. **Saccharopolyspora gloriosae** Qin, Chen, Klenk, Kim, Xu and Li 2010, 1150[VP]

glo.ri.o′sa.e. N.L. fem. gen. n. *gloriosae* of the plant genus *Gloriosa*, referring to the isolation of the type strain from a stem of *Gloriosa superba*.

Forms an extensively branched substrate mycelium. Curved and hooked chains of smooth-surfaced spores are formed on the aerial mycelium. Grows well on glycerol-asparagine (ISP medium 5), oatmeal (ISP medium 3), and yeast extract-malt extract (ISP medium 2) agars and moderately well on Czapek's and inorganic salts-starch (ISP medium 4) agars. Grows between 10 and 32°C (optimally at 28°C), pH 6.0 and 8.0, and in the presence of 0–11% NaCl (optimally with 0–5% salt).

Oxidase-negative. Adonitol, D-arabinose, arabitol, cellobiose, erythritol, esculin, fructose, gentiobiose, glycerol, glycogen, inositol, mannose, melezitose, starch, and trehalose are used as sole carbon sources. L-Alanine, D-arginine, L-asparagine, L-leucine, L-histidine, L-ornithine, L-proline, L-serine, and L-threonine are used as sole nitrogen sources. Additional phenotypic features are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$ iso, $C_{17:0}$ anteiso, and $C_{17:1}$ *cis*9. The predominant menaquinone is MK-9(H_4) and the major polar lipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, and several unknown phospholipids.

Source: isolated from a surface-sterilized stem of *Gloriosa superba* L.

DNA G+C content (mol%): 71.6 (HPLC).

Type strain: YIM 60513, KCTC 19243, CCTCC AA 207006.

Sequence accession no. (16S rRNA gene): EU005371.

7. **Saccharopolyspora gregorii** Goodfellow, Lacey, Athalye, Embley and Bowen 1989a, 496[VP] (Effective publication: Goodfellow, Lacey, Athalye, Embley and Bowen 1989b, 2137.)

gre.gor′i.i. N.L. gen. masc. n. *gregorii* of Gregory, named after P.H. Gregory, a British mycologist and aerobiologist.

Forms an extensively branched substrate mycelium, which fragments into coccoid elements. Sporulation or fragmentation of the aerial mycelium may sometimes be seen, forming hooks or flexuous chains of spores with smooth surfaces. Transmission electron micrographs show mainly vegetative rods and cocci, but occasionally spores with a smooth sheath are seen. Colonies are pale yellowish to buff with sparse white aerial mycelium at growth temperatures of about 20°C. Temperature range for growth is 10–35°C.

Degrades arbutin, gelatin, and Tweens 20 and 80. Adonitol, glycerol, D- and L-alanine, L-proline, propionate, and pyruvate are used as sole carbon sources, but not glycogen, trehalose, starch, or L-serine.

Resistant (µg/ml) to cephaloridine (2), lincomycin (16), oleandomycin (2), and benzylpenicillin (10), but sensitive to demecylocyline (2), gentamicin (4), neomycin (3), rifampin (2), streptomycin (4), tobramycin (8), and vancomycin (2). Grows in the presence of (%, w/v) bismuth citrate (0.001), crystal violet (0.0001), phenol (0.01), phenyl ethanol (0.1%, v/v), potassium tellurite (0.001), sodium azide (0.001), sodium chloride (13), tetrazolium (0.01), teepol (0.01), and thallous acetate (0.0001), but is sensitive to bismuth citrate (0.01), phenyl ethanol (0.4%, v/v), potassium tellurite (0.01), and thallous acetate (0.01). Additional phenotypic features are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$ iso, $C_{17:0}$ anteiso, and $C_{17:0}$ iso. The predominant menaquinone is MK-9(H_4) and the major polar lipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylglycerol, phosphatidylinositol, and uncharacterized phospho- and glycolipids.

Source: isolated from grass, hay, straw, barley grain, and soil.

DNA G+C content (mol%): 74 (T_m).

Type strain: A85, ATCC 51265, DSM 44324, NBRC 15045, NCIMB 12823, JCM 9687, NRRL B-16506.

Sequence accession no. (16S rRNA gene): X76962.

8. **Saccharopolyspora halophila** Tang, Wang, Cai, Zhi, Lou, Xu, Jiang and Li 2009a, 557[VP]

ha.lo′phi.la. Gr. n. *hals halos* salt; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *halophila* salt-loving, referring to the ability to grow at high NaCl concentrations.

Moderately halophilic. Forms a well-developed substrate mycelium that shows no evidence of fragmentation. Aerial hyphae differentiate into long straight chains of oval or spherical spores (0.6–0.7 × 0.6–1.1 µm) which have smooth

surfaces. The aerial mycelium is white-yellow in color and the substrate mycelium is yellow to moderate orange-yellow. Does not produce diffusible pigments. Grows well on Czapek's, glycerol-asparagine (ISP medium 5), inorganic salts-starch (ISP medium 4), potato, and yeast extract-malt extract (ISP medium 2) agars. Moderate growth occurs on nutrient and oatmeal (ISP medium 3) agars. Temperature, pH, and NaCl tolerance ranges are 10–45°C, pH 6–8.5, and 3–20% (w/v), respectively. Good growth occurs at 28–37°C, pH 7–8, and with 10–15% (w/v) NaCl.

Does not degrade cellulose. Liquefies gelatin. Milk peptonization and coagulation are positive. Does not produce H_2S. Acid is produced on L-arabinose, glucose, *myo*-inositol, rhamnose, and xylose. Cellobiose, *myo*-inositol, xylitol, and acetate are used as sole carbon sources, but not sorbitol or trehalose. Alanine, asparagine, arginine, cystine, glycine, histidine, homocysteine, hypoxanthine, lysine, proline, threonine, tyrosine, valine, and urea are utilized as sole nitrogen sources, but not adenine, hydroxyproline, or glutamate. Additional phenotypic features are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$ anteiso. The predominant menaquinone is MK-9(H_4) and the major polar lipids are diphosphatidylglycerol and phosphatidylcholine; large amounts of phosphatidylinositol are also present.

Source: isolated from a saline lake.

DNA G+C content (mol%): 66.3 (HPLC).

Type strain: DSM 45007, KCTC 19162, YIM 90500.

Sequence accession no. (16S rRNA gene): DQ923129.

9. **Saccharopolyspora hordei** Goodfellow, Lacey, Athalye, Embley and Bowen 1989a, 496[VP] (Effective publication: Goodfellow, Lacey, Athalye, Embley and Bowen 1989b, 2137.)

hor′de.i. L. n. *hordeum* barley, and also the generic name of barley (*Hordeum*); L. gen. n. *hordei* from barley, referring to the isolation source of the strains.

Forms an extensively branched substrate mycelium which sometimes fragments into coccoid elements. Aerial mycelium is either not produced or is sparse and is white with short flexuous, hooked, or spiral spore chains often with a beaded appearance. Transmission electron micrographs show that the spores are covered by a smooth sheath with adjacent spores often separated by a short length of empty hypha. Colonies are colorless to light buff, conical, rounded, or wrinkled. Grows at 20–60°C.

Resistant (μg/ml) to lincomycin (16), neomycin (3), oleandomycin (16), benzylpenicillin (10), and tobramycin (4), but sensitive to cephaloridine (10), demeclocycline (2), gentamicin (16), rifampin (2), streptomycin (4), and vancomycin (2). Arbutin, DNA, guanine, RNA, testosterone, and Tweens 20 and 80 are degraded. Does not hydrolyze allantoin. Cellobiose, glycogen, glycerol, and starch are used as sole carbon sources. Grows well in the presence of (%, w/v) bismuth citrate (0.0001), crystal violet (0.0001), phenol (0.1), phenyl ethanol (0.2%, v/v), potassium tellurite (0.001), sodium azide (0.001), sodium chloride (10), teepol (0.01), tetrazolium (0.01), and thallous acetate (0.0001), but is sensitive to bismuth citrate (0.01), phenyl ethanol (0.4%, v/v), potassium tellurite (0.01), sodium azide (0.02), and thallous acetate (0.01). Additional phenotypic features are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$ iso, $C_{17:0}$ anteiso, and $C_{17:0}$ iso. The predominant menaquinone is MK-9(H_4) and the major polar lipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylglycerol, phosphatidylinositol, and uncharacterized phospho- and glycolipids.

Source: isolated from barley and oat grains, grass hay, straw, and sugar cane bagasse.

DNA G+C content (mol%): 72 (T_m).

Type strain: A54, ATCC 49856, DSM 44065, NBRC 15046, JCM 8090, NCIMB 12824, NRRL B-16507.

Sequence accession no. (16S rRNA gene): X53197.

10. **Saccharopolyspora jiangxiensis** Zhang, Wu and Liu 2009, 1078[VP]

ji.ang.xi.en′sis. N.L. fem. adj. *jiangxiensis* pertaining to Jiangxi Province, China, the source of the grass-field soil from which the organism was isolated.

Produces an extensively branched (0.4–0.7 μm diameter), colorless to buff substrate mycelium which fragments *in situ* into coccoid- and rod-shaped elements after 3–4 d at 28°C. White to buff aerial hyphae (0.6–1.0 μm in diameter) are produced upon prolonged cultivation on GYM agar. The aerial mycelium carries long straight to flexuous chains of 6–10 spores (spore size 0.8–1.1 × 1.0–1.3 μm). The spore surface is smooth or irregularly rough. Colony elevation is convex to irregular and colony margins are filamentous. Does not form diffusible pigments. Grows well on GYM, inorganic salts-starch (ISP medium 4), oatmeal (ISP medium 3), and modified Sauton's agars, and at 15–45°C and pH 5.5–9.5. Weak growth occurs in the presence of NaCl at 11%, but not at 12% (w/v).

Does not degrade cellulose, guanine, or xylan. Catalase- and arbutin-positive. Acid is formed from adonitol, D-arabinose, dextrin, D-fructose, D-galactose, D-glucose, glycerol, inulin, maltose, D-mannitol, D-mannose, D-ribose, sucrose, and trehalose, but not from L-arabinose, cellobiose, ethanol, *meso*-erythritol, glycogen, *myo*-inositol, D-lactose, melezitose, melibiose, methyl α-D-glucoside, raffinose, α-L-rhamnose, D-salicin, D-sorbitol, or D-xylose. Adonitol, D-arabinose, *meso*-erythritol, methyl α-D-glucoside, *myo*-inositol, melezitose, sorbitol, trehalose, acetate, benzoate, citrate, fumarate, malate, succinate, and tartrate are used as sole carbon sources, but not salicin, malonate, or oxalate.

Resistant (μg per disc) to amoxycillin plus clavulanic acid (10), ampicillin (10), aztreonam (30), clindamycin (2), erythromycin (15), kanamycin (30), penicillin G (10 U), and tobramycin (10), but susceptible to amikacin (30), cefotaxime (30), chloramphenicol (30), ciprofloxacin (5), gentamicin (10), mezlocillin (75), ofloxacin (5), rifampin (5), streptomycin (10), and tetracycline (30). Grows in the presence of lysozyme (0.005%, w/v). Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic

acid as the major diamino acid. Cellular fatty acids contain major proportions of $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{17:0}$ anteiso. The predominant menaquinone is MK-9(H_4) and the major polar lipids are phosphatidylcholine, phosphatidylethanolamine, and phosphatidylglycerol.

DNA relatedness values between the type strain and corresponding strains of closely related species are as follows: *Saccharopolyspora antimicrobica*, 56.3%; *Saccharopolyspora hirsuta*, 47.8%; *Saccharopolyspora shangdongensis*, 25.5%; and *Saccharopolyspora spinosa*, 21.7%.

Source: isolated from a soil sample from a grass field.

DNA G+C content (mol%): 70.3 (T_m).

Type strain: CGMCC 4.3529, JCM 14613, W12.

Sequence accession no. (16S rRNA gene): EF143926.

11. **Saccharopolyspora phatthalungensis** Duangmal, Mingma, Thamchaipenet, Matsumoto and Takahashi 2010, 1907[VP]

phat.tha.lun.gen′sis. N.L. fem. adj. *phatthalungensis* referring to Phatthalung Province, Thailand, the source of the rhizospheric soil from which the organism was isolated.

Forms an extensively branched substrate mycelium which is yellowish to yellowish brown on glycerol-asparagine (ISP medium 5), glucose-yeast extract, inorganic salts-starch (ISP medium 4), peptone-yeast extract iron (ISP medium 5), tyrosine (ISP medium 7), tryptone-yeast extract (ISP medium 1), and yeast extract-malt extract (ISP medium 2) agars. A white aerial mycelium is produced on these media and a brownish-black soluble pigment is produced on ISP medium 2. Spores with spiny surfaces are borne in hooks/open loops. Grows between 18 and 42°C (optimally at 28–34°C) and between pH 5.0 and 9.0. Grows well on ISP medium 2 supplemented with 1–5% (w/v) NaCl, moderately well with 6% (w/v) NaCl, and poorly in the presence of 7% (w/v).

Gelatin is degraded, but not arbutin, cellulose, or guanine. Catalase-positive, but does not hydrolyze allantoin. H_2S is produced. Acid is produced from adonitol, fructose, galactose, glucose, glycerol, *myo*-inositol, mannitol, mannose, ribose, trehalose, and xylose (weakly), but not from arabinose, cellobiose, fucose, β-lactose, maltose, melibiose, rhamnose, raffinose, sorbitol, sorbose, sucrose, or xylitol. Positive for alkaline phosphatase and leucine aminopeptidase, but negative for acid phosphatase, α-chymotrypsin, cystine aminopeptidase, esterase (C4), α-fucosidase, α-galactosidase, β-galactosidase, α-glucosidase, β-glucosidase, β-glucuronidase, lipase (C8), lipase (C14), α-mannosidase, *N*-acetyl-β-glucosaminidase, trypsin phosphoamidase, and valine aminopeptidase (API ZYM tests). Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. The glycan moiety of the peptidoglycan is acetylated. Cellular fatty acids contain major proportions of $C_{16:0}$ and 10-methyl $C_{17:0}$. The predominant menaquinone is MK-9(H_4) and the major polar lipids are phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol.

Source: isolated from rhizospheric soil.

DNA G+C content (mol%): 70.3 (HPLC).

Type strain: BCC 35844, NRRL B-24798, SR8.15, TISTR 1921.

Sequence accession no. (16S rRNA gene): GQ381309.

12. **Saccharopolyspora qijiaojingensis** Tang, Wang, Wu, Cao, Lou, Xu, Jiang and Li 2009b, 2168[VP]

qi.ji.a.o.jing.en′sis. N.L. fem. adj. *qijiaojingensis* pertaining to Qijiaojing Lake, Xinjiang Province, north-west China, where the sample from which the type strain was isolated was collected.

Moderately halophilic. Forms a well-developed substrate mycelium that fragments into rod-shaped elements. Bead-like straight chains of smooth surfaced spores (0.6–0.7 × 0.7–1.1 µm in size) are formed on the aerial mycelium. Temperature, pH, and NaCl ranges for growth are 20–40°C, pH 5.0–8.0, and 6–22% (w/v) NaCl; optimal growth occurs at 28°C, pH 7.0, and 10–15% (w/v) NaCl.

Gelatin and Tween 20 are degraded, but not cellulose or Tween 80. Does not peptonize or coagulate milk or produce H_2S. Trehalose is used as a sole carbon source, but not cellobiose, glycerol, glycogen, or starch. DL-Alanine, L-hydroxyproline, hypoxanthine, L-histidine, L-asparagine, and xanthine are utilized as nitrogen sources, but not L-lysine, L-serine, adenine, L-tyrosine, or L-phenylalanine.

Resistant (µg per disc) to gentamicin (10), streptomycin (10), sulfamethoxazole/trimethoprin (23.75/1.25), and tobramycin, but sensitive to amoxycillin (10), ampicillin (10), chloroamphenicol (30), ciprofloxacin (5), erythromycin (15), rifampin (5), tetracycline (30), and vancomycin (30). Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{15:0}$ iso, $C_{16:0}$ iso, and $C_{17:0}$ iso. The predominant menaquinone is MK-9(H_4) and the major polar lipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylinositol mannosides, and an unknown phospholipid.

Source: isolated from a salt lake.

DNA G+C content (mol%): 70.1 (HPLC).

Type strain: DSM 45088, KCTC 19235, YIM 91168.

Sequence accession no. (16S rRNA gene): EF687715.

13. **Saccharopolyspora rectivirgula** (Krasil'nikov and Agre 1964) Korn-Wendisch, Kempf, Grund, Kroppenstedt and Kutzner 1989, 439[VP] [*Faenia rectivirgula* (Cross, Maciver and Lacey 1968) Kurup and Agre 1983, 664; *Micropolyspora faeni* (Corbaz, Gregory and Lacey 1963) Cross, Maciver and Lacey 1968, 354; Basonym: *Micropolyspora rectivirgula* (Krasil'nikov and Agre 1964) Prauser and Momirova 1970, 220; *Thermopolyspora polyspora* Corbaz, Gregory and Lacey 1963, 450; *Thermopolyspora polyspora* Henssen 1957, 396; *Thermopolyspora rectivirgula* Krasil'nikov and Agre 1964, 106]

rec.ti.vir′gu.la. L. adj. *rectus* straight; L. n. *virgula* twig; N.L. n. *rectivirgula* straight twig.

Forms chains of spores on both substrate and aerial hyphae. The spores are borne on short, unbranched, lateral, or terminal sporophores. Spore formation is basipetal and spore surfaces are rough. Substrate hyphae are branched, septate, 0.5–0.8 µm in diameter, and yellow to orange on GYM and TS agars. Similarly, a white to pink aerial mycelium is formed on these media: aerial hyphae are especially well developed in the presence of 5% (w/v) NaCl. Grows

at 37–63°C (optimally at 50°C) and in the presence of 10% (w/v) NaCl.

Degrades gelatin, but not xylan. Allantoin and uric acid are hydrolyzed, but hemolysis and egg yolk reactions are negative. Sensitive to lysozyme. Fructose and inositol are used as sole carbon sources. Lysed by the five lytic *Saccharopolyspora rectivirgula* phages (e.g. P113); nonlysogenic strains are lysed by all temperate *Saccharopolyspora rectivirgula* phages (e.g. ϕFR114 and ϕFR-C) and three *Saccharopolyspora erythraea* phages (e.g. P517). Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. The predominant menaquinone is MK-9(H_4) and the major polar lipids are phosphatidylcholine, phosphatidylethanolamine, and phosphatidylmethylethanolamine.

Causative agent of farmer's lung disease.

Source: isolated from moldy hay, soil, compost, and manure.

DNA G+C content (mol%): 70.4 (HPLC).

Type strain: ATCC 33515, BKM A-810, DSM 43747, NBRC 12464, INMI 683, JCM 3057, NRRL B-16280, VKM Ac-810.

Sequence accession no. (16S rRNA gene): X53194.

14. **Saccharopolyspora rosea** Yassin 2009, 1151[VP]

ro.se′a. L. fem. adj. *rosea* rose-colored, pink, referring to the color of the diffusible pigment produced by the organism.

Forms extensively branched, brownish-yellow substrate hyphae (0.4–0.5 µm in diameter) which fragment into rod-shaped elements. Yellowish to white aerial hyphae (0.5–0.7 µm in diameter) differentiate into long straight chains of smooth-surfaced spores. Pink colored diffusible pigments are produced on oatmeal (ISP medium 3), inorganic salts-starch (ISP medium 4), and yeast extract-malt extract (ISP medium 2) agars, but does not form melanin pigments on peptone-yeast extract iron (ISP medium 6) or tyrosine (ISP medium 7) agars. Grows at 22–42°C and pH 6.0–9.0.

Gelatin is degraded, but not guanine, keratin, or testosterone. Catalase-positive and oxidase-negative. Acetate, adipate, adonitol, isoamyl alcohol, 2,3-butanediol, citrate, *meso*-erythritol, D-gluconate, *myo*-inositol, L-lactate, sorbitol, and trehalose are used as sole carbon sources, but not cellobiose, *m*-hydroxybenzoate, *p*-hydroxybenzoate, lactose, melezitose, or 1,2-propanediol. Acetamide, L-alanine, arginine, gelatin, ornithine, L-proline, and L-serine are used as simultaneous sources of carbon and nitrogen. Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{17:0}$ anteiso. The predominant menaquinone is MK-9(H_4) and the major polar lipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol.

Source: isolated from a bronchial lavage of patient with bronchial carcinoma.

DNA G+C content (mol%): unknown.

Type strain: DSM 45226, CCUG 56401, IMMIB L-1070.

Sequence accession no. (16S rRNA gene): AM992060.

15. **Saccharopolyspora shandongensis** Zhang, Wu, Zhang, Liu and Song 2008b, 1096[VP]

shan.dong.en′sis. N.L. fem. adj. *shandongensis* referring to Shandong Province, China, the source of the wheat-field soil from which the type strain was isolated.

Forms an extensively branched substrate mycelium (0.5–0.8 µm in diameter) which fragments *in situ* into coccoid- and rod-shaped elements after 3–4 d at 28°C. White aerial hyphae (0.7–1.0 µm in diameter) are produced upon prolonged cultivation on glucose-yeast extract-malt agar. The aerial mycelium carries abundant spiral chains of ten or more spiny-surfaced spores (0.8–1.0 × 1.0–1.2 µm) in a spiral arrangement. Grows well on oatmeal (ISP medium 3) and Sauton's agars. A brown diffusible pigment is formed on standard media. Grows at 15–38°C and pH 5.5–9.5. Weak growth occurs in the presence of 7% (w/v) NaCl, but no growth occurs in the presence of 8% (w/v) NaCl.

Does not degrade cellulose, guanine, or xylan. Catalase- and arbutin-positive. Acid is formed from adonitol, D-arabinose, cellobiose, dextrin, D-fructose, D-glucose, glycerol, maltose, D-mannitol, D-mannose, melibiose, D-ribose, and trehalose, but not from L-arabinose, ethanol, *meso*-erythritol, D-galactose, glycogen, *myo*-inositol, inulin, D-lactose, melezitose, methyl α-D-glucoside, raffinose, α-L-rhamnose, D-salicin, D-sorbitol, sucrose, or D-xylose. Adonitol, D-arabinose, cellobiose, *meso*-erythritol, D-fructose, D-glucose, glycerol, D-mannitol, D-mannose, methyl α-D-glucoside, melibiose, D-sorbitol, trehalose, acetate, benzoate, citrate, succinate, and tartrate are used as sole carbon sources, but not *myo*-inositol, melezitose, D-salicin, fumarate, malate, malonate, or oxalate.

Resistant (µg per filter paper disc) to aztreonam (30), clindamycin (2), and penicillin G (10 IU), but susceptible to amikacin (30), amoxycillin plus clavulanic acid (10), ampicillin (10), cefotaxime (30), chloramphenicol (30), ciprofloxacin (5), erythromycin (15), gentamicin (10), kanamycin (30), mezlocillin (75), ofloxacin (5), rifampin (5), streptomycin (10), tetracycline (30), and tobramycin (10). Grows in the presence of lysozyme (0.0005%, w/v). Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the major diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$ iso, $C_{17:0}$ anteiso, $C_{18:0}$ iso, $C_{17:1}$ ω8*c*, and $C_{17:0}$ iso. The predominant menaquinone is MK-9(H_4) and the diagnostic polar lipid is phosphatidylcholine.

The DNA–DNA relatedness value between the type strain and the corresponding strain of *Saccharopolyspora spinosa*, a closely related species, is 32.8%.

Source: isolated from wheat-field soil.

DNA G+C content (mol%): 70.1 (T_m).

Type strain: 88, CGMCC 4.3530, JCM 14614.

Sequence accession no. (16S rRNA gene): EF104116.

16. **Saccharopolyspora spinosa** Mertz and Yao 1990, 38[VP]

spi.no′sa. L. fem. adj. *spinosa* spiny, referring to the spiny spore sheath surface.

Forms an extensive substrate mycelium which fragments in liquid media. Well-formed aerial hyphae segment into long chains of spores arranged in hooks and open loops. Short and incomplete spiral spore chains are also seen. The

spores (1.1 × 1.5 µm) have spiny surfaces. Aerial hyphae have a distinctive bead-like appearance with many empty spaces in the spore chains. The aerial mycelium is yellowish pink and the vegetative mycelium is yellow to yellowish brown. A soluble brown pigment is produced on some media. The temperature range for growth is 15 to 37°C. Does not survive a temperature of 50°C for 8 h. Growth occurs in the presence of 11% NaCl.

Allantoin, malate, and testosterone are degraded, but not guanine. Catalase- and phosphatase-positive. Acid is produced from adonitol, D-arabinose, *meso*-erythritol, D-fructose, D-glucose, glycerol, D-mannitol, D-mannose, D-ribose, and trehalose, but not from L-arabinose, cellobiose, cellulose, dextrin, dulcitol, ethanol, D-galactose, glycogen, inositol, inulin, lactose, maltose, melezitose, melibiose, methyl α-D-glucoside, raffinose, L-rhamnose, salicin, D-sorbitol, L-sorbose, sucrose, xylitol, or D-xylose. Acetate, butyrate, citrate, formate, lactate, malate, propionate, pyruvate, and succinate are used as sole carbon sources, but not benzoate, mucate, oxalate, or tartrate.

Resistant to (µg per disc) cephalothin (20), kasugamycin (500), nalidixic acid (30), novobiocin (20), oligomycin (100), oxytetracycline (10), penicillin (10 U), polymixin B (300 U), rifampin (5), and trimethoprim (30), but sensitive to bacitracin (10 U), chloromycetin (30), erythromycin (15), gramicidin S (10), gentamicin (10), kanamycin (10), lincomycin (2), mandelamine (3), mikamycin A and B (10), neomycin (30), oleandomycin (15), spiramycin (10), streptomycin (10), tetracycline (30), thiostreptin (10), tobramycin (10), timicamycin (5), valinomycin (10), and vancomycin (30). Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. The predominant menaquinone is MK-9(H_4) and the major polar lipids are cardiolipin and phosphatidylcholine.

Source: isolated from soil collected from a sugar mill rum still.

DNA G+C content (mol%): not known.

Type strain: A83543.1, ATCC 49460, DSM 44228, JCM 9375, NBRC 15153, NRRL 18395.

Sequence accession no. (16S rRNA gene): AF002818.

17. **Saccharopolyspora spinosporotrichia** Zhou, Liu, Qian, Kim and Goodfellow 1998, 56[VP]

spi.no.spo.ro.tri′chi.a. L. adj. *spinosus* thorny; N.L. n. *spora* a spore; N.L. n. *trichia* trichite; N.L. n. *spinosporotrichia* spores bearing needle-like spines.

Forms an extensively branched, reddish-brown substrate mycelium that fragments into rod-shaped elements. An abundant white to gray aerial mycelium bears long spiral chains of spherical spores with warty surfaces. Grows well on Bennett's, Czapek's, Gause's synthetic, inorganic salts-starch (ISP medium 4), oatmeal (ISP medium 3), and sucrose-yeast extract agars. A brown diffusible pigment is formed on most standard media. Grows between 25 and 37°C and in the presence of 2–3% (w/v) sodium chloride.

Glycerol, *myo*-inositol, melibiose, ribose, and sorbitol are used as sole carbon sources, but not sorbose. Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the predominant diamino acid. The predominant menaquinone is MK-9(H_4); the polar lipid profile includes major amounts of phosphatidylcholine.

Source: isolated from soil.

DNA G+C content (mol%): 70.4 (T_m).

Type strain: AS4.198, DSM 44350, NBRC 16190, JCM 10303.

Sequence accession no. (16S rRNA gene): Y09571.

18. **Saccharopolyspora taberi** (Labeda 1987) Korn-Wendisch, Kempf, Grund, Kroppenstedt and Kutzner 1989, 439[VP] (Basonym: *Saccharopolyspora hirsuta* subsp. *taberi* Labeda 1987, 21; *Saccharopolyspora hirsuta* subsp. *kobensis* Iwasaki, Itoh and Mori 1979, 185.)

ta′ber.i. N.L. gen. masc. n. *taberi* of Taber, named after Willard A. Taber, the American microbiologist who first isolated the organism.

Forms a substrate mycelium that ranges from yellow to orange and from reddish to brownish red on glucose-yeast extract and tryptic soy agars. Neither aerial hyphae nor spores have been detected. Grows from 20 to 45°C, optimally at 37°C. Grows poorly in the presence of 7% NaCl.

Degrades gelatin, but not DNA. Allantoin, arbutin, and uric acid are hydrolyzed. Negative for hemolysis and for the egg yolk reaction. Inositol is used as a sole carbon source.

The dark red metabolite texazone [2-(*N*-methylamino)-3H-phenoxazin-3-one-8-carboxylic acid] is produced. Lysed by three *Saccharopolyspora erythraea* phages (e.g. P517) and four temperate *Saccharopolyspora rectivirgula* phages (e.g. ϕFR-C). Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{16:0}$ iso, $C_{17:0}$ iso, $C_{15:0}$ iso, and $C_{17:0}$ anteiso. The predominant menaquinone is MK-9(H_4) and the major polar lipids are diphosphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylmethylethanolamine, and hydroxyphosphatidylethanolamine.

Source: isolated from soil.

DNA G+C content (mol%): 70.8 (HPLC).

Type strain: ATCC 49842, DSM 43856, NBRC 15061, JCM 9383, LL-WRAT-210, NRRL B-16173.

Sequence accession no. (16S rRNA gene): AF002819.

19. **Saccharopolyspora thermophila** Lu, Liu, Wang, Zhang, Qi and Goodfellow 2001, 322[VP]

ther.mo′phi.la. Gr. n. *thermê* heat; N.L. adj. *philus -a -um* (from Gr. adj. *philos -ê -on*) friend, loving; N.L. fem. adj. *thermophila* heat-loving.

Forms an extensively branched colorless to buff substrate mycelium that fragments into rod-shaped elements after 4–5 d at 45°C and an abundant aerial mycelium which carries long hooked to flexuous chains of 4–6 smooth-surfaced, vesicular spores (0.7–1.1 × 0.85–1.5 µm). Grows well on oatmeal, modified Sauton's, and yeast extract-malt extract (ISP medium 2) agars. Does not produce diffusible pigments. The temperature growth range is 45–55°C. Growth occurs in the presence of 7% (w/v) NaCl.

Degrades guanine and xylan, but not cellulose. Adonitol, cellobiose, erythritol, glycerol, inositol, melezitose, methyl α-D-glucoside, salicin, sorbitol, trehalose, acetate, adipate, benzoate, butyrate, citrate, fumarate, H-malate, propionate, pyruvate, sebacic acid, and succinate are used as sole carbon sources, but not tartrate.

Inhibited by lysozyme, gentamicin, streptomycin, and rifampin. Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. The predominant menaquinones are MK-9(H_6) and MK-9(H_8); the polar lipid pattern contains phosphatidylcholine.

Source: isolated from grassland soil.

DNA G+C content (mol%): 73.1 (T_m).

Type strain: 216, AS4.1511, DSM 44575, NBRC 16346, JCM 10664.

Sequence accession no. (16S rRNA gene): AF127526.

20. **Saccharopolyspora tripterygii** Li, Zhao, Qin, Huang, Zhu, Xu and Li 2009a, 3042[VP]

trip.te.ry′gi.i. N.L. n. *Tripterygium* a botanical genus name; N.L. gen. n. *tripterygii* of *Tripterygium*, the plant genus from which this species was isolated.

Forms an extensively branched substrate mycelium and an aerial mycelium which carries long spore chains. Spores are elliptical or short rods (0.5–0.8 × 1.0–1.5 µm) with smooth surfaces. Grows well on glycerol-asparagine (ISP medium 5), inorganic salts-starch (ISP medium 4), potato, and yeast extract-malt extract (ISP medium 2) agars, and moderately well on Czapek's, nutrient, and oatmeal (ISP medium 3) agars. Soluble pigments are not produced. The substrate mycelium is orange-yellow and the aerial mycelium is white on most of the media cited above. Grows at 10–37°C and pH 7.0–8.0. The NaCl tolerance range is up to 12% (w/v).

Degrades Tweens 20 and 40, but not cellulose or gelatin. Catalase-positive, but does not coagulate or peptonize milk or produce H_2S. Acid is produced from amygdalin and esculin, but not from cellobiose, dulcitol, inositol, mannose, oxalate, or sorbitol. D-Arabinose, ribose, acetate, and citrate are used as sole carbon sources. Adenine, L-arginine, L-hydroxyproline, hypoxanthine, L-lysine, L-phenylalanine, L-serine, L-tyrosine, and L-valine are used as sole nitrogen sources, but not L-alanine, glycine, or xanthine. Additional phenotypic properties are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal acid. Cellular fatty acids contain major proportions (>10%) of $C_{15:0}$ iso, $C_{17:0}$ anteiso, $C_{18:0}$ iso, and $C_{17:0}$ iso. The predominant menaquinone is MK-9(H_4) and the major polar lipids are phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, phosphatidylinositol mannosides, phosphatidylmethylethanolamine, and one unknown phospholipid.

DNA–DNA relatedness values (± SD) between the type strain and corresponding strains of closely related species are as follows: "*Saccharopolyspora endophytica*", 57.5 ± 4.5%; *Saccharopolyspora flava*, 44.9 ± 3.5%; and *Saccharopolyspora spinosa*, 48.5 ± 3.0%.

Source: isolated from a surface-sterilized stem sample of *Tripterygium hypoglaucum*.

DNA G+C content (mol%): 70.5 (HPLC).

Type strain: CCTCC AA 208062, DSM 45269, YIM 65359.

Sequence accession no. (16S rRNA gene): FJ214364.

Species *incertae sedis*

1. **"Saccharopolyspora endophytica"** Qin, Li, Zhao, Chen, Xu and Li 2008a, 354

en.do.phy′ti.ca. Gr. adj. *endo* inside; Gr. *phyton* plant; L. fem. suff. *-ica*, adjectival suffix used with the sense of belonging to; N.L. fem. adj. *endophytica* within plant, pertaining to the original isolation from plant tissues.

Forms an extensively branched substrate mycelium. Long, smooth-surfaced spores are borne in straight chains or loose spirals on the aerial mycelium. Grows well on Czapek's, glycerol-asparagine (ISP medium 5), potato, and yeast extract-malt extract (ISP medium 2) agars. White aerial hyphae are formed on most of these media and pink diffusible pigments are formed on some agar media. NaCl tolerance range is 0–15% (w/v). Temperature and pH ranges for growth are 20–45°C and pH 5.0–9.0, respectively. Optimal temperature and pH for growth are 37°C and pH 7.0–7.5, respectively.

Cellulose, chitin, hypoxanthine, starch, tyrosine, Tweens 20 and 80, and xanthine are degraded, but not casein. Milk is not coagulated or peptonized. Does not hydrolyze esculin or urea, or produce H_2S. Cellobiose, dextrin, erythritol, inositol, malate, ribose, sorbitol, starch, trehalose, and xylitol are used as sole carbon sources, but not dulcitol, glycine, oxalate, propionate, sorbose, or succinate. Additional phenotypic features are shown in Table 255.

Whole-organism hydrolysates contain arabinose and galactose as characteristic sugars and *meso*-diaminopimelic acid as the principal diamino acid. Cellular fatty acids contain major proportions of $C_{15:0}$ iso, $C_{16:0}$ iso, $C_{17:0}$ iso, and $C_{17:0}$ anteiso. The predominant menaquinone is MK-9(H_4) and the major polar lipds are diphphatidylglycerol, phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides.

The DNA–DNA relatedness value between the type strain and the corresponding strain of *Saccharopolyspora flava*, a closely related species, is 31%.

Source: isolated from surface-sterilized root of *Maytenus austroyunnanensis*.

DNA G+C content (mol%): 66.2 (HPLC).

Type strain: YIM 61095, KCTC 19397, CCTCC AA 208003.

Sequence accession no. (16S rRNA gene): EU814512.

Genus XV. **Saccharothrix** Labeda, Testa, Lechevalier and Lechevalier 1984, 429[VP] emend. Labeda and Lechevalier 1989, 422

David P. Labeda

Sac.cha.ro′thrix. Gr. n. *sakchâr* sugar; Gr. fem. n. *thrix* hair; N.L. fem. n. *Saccharothrix* sugar-containing hair.

Branched vegetative mycelia (approximately 0.5–0.7 μm diameter); aerial mycelium is produced on some growth media. Both the vegetative and aerial hyphae fragment into coccoid to coccoid-rod, nonmotile elements. A "zig-zag" morphology of the aerial hyphae is typically observed during sporulation of most species. Gram-stain-positive. Resistant to lysozyme. Catalase-positive and aerobic. **Cell wall contains *meso*-diaminopimelic acid. Characteristic whole-cell sugars consist of galactose, rhamnose, and a trace of mannose. The phospholipid pattern contains significant amounts of phosphatidylethanolamine and phosphatidylethanolamine containing 2-hydroxy fatty acids, as well as diphosphatidylglycerol, phosphatidylglycerol, phosphatidylinositol, and phosphatidylinositol mannosides. The principal menaquinones are MK-9(H_4) and MK-10(H_4).** The fatty acid profile consists predominantly of iso- and anteiso-pentadecanoic, hexadecanoic, and heptadecanoic saturated fatty acids along with smaller quantities of unsaturated, straight-chain pentadecanoic, hexadecanoic, and heptadecanoic fatty acids. Phylogenetically, the genus *Saccharothrix* represents a line of descent closest to the genera *Lentzea* and *Lechevalieria*. **The 16S rRNA gene sequence contains the genus-specific diagnostic nucleotide signature pattern of CAC (607–609) and GTG (617–619).**

DNA G+C content (mol%): 67–76 (T_m).

Type species: **Saccharothrix australiensis** Labeda, Testa, Lechevalier and Lechevalier 1984, 430[VP].

TABLE 256. Secondary metabolites produced by the type strains of *Saccharothrix* species

Species	Compound or activity
Saccharothrix algeriensis	Dithiolopyrrolone antibiotics
Saccharothrix australiensis	Antibiotic LL-BM-782-β
Saccharothrix espanaensis	Antibiotic LL-C19004-α
Saccharothrix mutabilis subsp. *capreolus*	Antibiotic capreomycin
Saccharothrix mutabilis subsp. *mutabilis*	Antibiotic polynitoxin
Saccharothrix syringae	Antibiotic nocamycin
Saccharothrix xinjiangensis	Degrades pyrene

Further descriptive information

After the initial description of the genus *Saccharothrix* by Labeda et al. (1984), numerous species were transferred to this genus from other taxa, such as *Actinomadura* and *Nocardiopsis*, based on chemotaxonomic and morphological criteria. The number of species in this genus with validly published names has decreased in recent years as a result of taxonomic reclassifications based on molecular phylogenetic studies and reassessment of chemotaxonomic data. In this regard, *Crossiella cryophila*, *Goodfellowiella coeruleoviolacea*, *Lechevalieria aerocolonigenes*, *Lechevalieria flava*, *Lentzea waywayandensis*, and *Umezawaea tangerina* were all valid species within the genus *Saccharothrix* but were subsequently reclassified (Labeda, 2001; Labeda et al., 2001; Labeda and Kroppenstedt, 2006, 2007) as phylogenetic relationships based on analyses of the 16S rRNA gene were understood. In all of these taxa, a careful re-examination of the chemotaxonomic profiles found differences from that of *Saccharothrix sensu stricto* which were supportive of description as members of new or other existing genera.

Members of the genus *Saccharothrix* have been of great interest as sources of novel secondary metabolites and many of the species were isolated and described as a function of natural products discovery programs in the pharmaceutical industry. The antibiotics produced and the biotechnological activities shown by the type strains of several species of *Saccharothrix* can be seen in Table 256.

Enrichment and isolation procedures

Strains of *Lechevalieria*, *Lentzea*, and *Saccharothrix* have been isolated from soil samples by spread-plating serial soil dilutions onto routine selective media (such as 1.5% crude agar and 0.4% casein hydrolysate in tap water) used for the general isolation of actinomycetes. Shearer (1987) reported the use of typical actinomycete isolation media, such as Gauze mineral medium no. 1 (Gauze et al., 1957) or starch-casein agar (Küster and Williams, 1964), supplemented with 5–10 μg/ml penicillin G and 15 μg/ml nalidixic acid antibiotics to selectively isolate *Saccharothrix* strains. *Saccharothrix algeriensis* was isolated from a Saharan soil sample by plating soil dilutions on the humic acid-vitamin medium of Hayakawa and Nonomura (1987) supplemented with streptomycin sulfate (10 μg/ml) and cycloheximide (50 μg/ml) (Zitouni et al., 2004). More recently, the pyrene-degrading species *Saccharothrix xinjiangensis* was isolated from filtered water samples (0.22 μm pore size) from Tianchi Lake by plating serial dilutions onto agar plates with anthracene, benzene, phenathrene, or pyrene as the sole carbon source (Hu et al., 2004).

Maintenance procedures

Working cultures of *Saccharothrix* can be maintained as refrigerated (4°C) agar slants on an appropriate medium such as NZamine medium (DSMZ medium 554; DSMZ, 2001). The slants are generally incubated for 5–7 d at 28–30°C prior to refrigeration and then should be subcultured at monthly intervals. Longer term preservation of strains is best accomplished as frozen stocks in 20% (v/v) aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques.

Procedures for testing special characters

Strains are routinely cultivated on NZamine medium (DSMZ medium 554) at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and NZamine medium.

Chemotaxonomic analyses of strains for fatty acids, polar lipids, and menaquinones are performed using methods previously described by Grund and Kroppenstedt (1989), Minnikin et al. (1984), Saddler et al. (1991), and Sasser (1990).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, guanine, hippurate, hypoxanthine, tyrosine, xanthine, and urea, are typically determined using the media of Gordon et al. (1974). Phosphatase activity is evaluated by using the method of Kurup and Schmitt

(1973) substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of NZamine medium and salt tolerance is determined on slants of the same medium supplemented with 4% and 5% NaCl.

Differentiation of the genus *Saccharothrix* from other genera

The type strains of the species of the genus *Saccharothrix* form a monophyletic lineage that is distinct from the genera *Actinosynnema*, *Lechevalieria*, and *Lentzea* and closest to, but distinct from, the genus *Umezawaea* (see Figure 290). The aligned sequences of the 16S rRNA genes for *Saccharothrix*, *Actinosynnema*, *Lechevalieria*, *Lentzea*, and *Umezawaea* (see Figure 309 in the treatment of the genus *Lechevalieria*) illustrate that *Saccharothrix* strains can easily be distinguished from those of other genera on the basis of the diagnostic nucleotide signatures CAC (607–609) and GTG (617–619). Salazar et al. (2002) also reported a set of specific PCR primers for the genus *Saccharothrix*, Stx2 (5′-AAGGCCCTTCGGGGTACACGAG-3′) and Stx1 (5′-TCGACCGCAGGCTCCACG-3′), that with a PCR annealing temperature of 66°C permitted the rapid detection of all species except *Saccharothrix texasensis*.

The species of the genus *Saccharothrix* can be distinguished chemotaxonomically from those of the genera *Lechevalieria*, *Lentzea*, and *Umezawaea* by the presence of phosphatidylethanolamine containing 2-hydroxy fatty acids in their phospholipid profiles (see Table 257), similar to the genus *Actinosynnema* from which they can be easily distinguished. *Saccharothrix* species can be differentiated from other phylogenetically related genera by the presence of galactose, rhamnose, and a trace of mannose as their whole-cell sugar pattern and the presence of both MK-9(H_4) and MK-10(H_4) as their predominant menaquinones (see Table 257).

Saccharothrix strains produce aerial mycelium on some growth media and both the substrate and aerial hyphae fragment into coccoid to coccoidal-rod-shaped elements. Sporangia, coremia, or motile spores are not produced, which differentiates *Saccharothrix* strains from members of the genera *Actinosynnema* and *Actinokineospora*.

Differentiation of the species of the genus *Saccharothrix*

The physiological characteristics of *Saccharothrix* species are summarized in Table 258 and can be used to differentiate between species, although a common set of physiological tests has not been used in the description of all species. Gross colonial morphology provides some additional information on the species based on the color of the substrate mycelium, production and color of aerial mycelium, and production and color of soluble pigments when grown on agar media.

TABLE 257. Chemotaxonomic characteristics of *Saccharothrix* and related genera[a]

Character	*Saccharothrix*	*Actinosynnema*	*Lechevalieria*	*Lentzea*	*Umezawaea*
Whole-cell sugar pattern[b]	Gal, Rha, Man (trace)	Gal, Man	Gal, Man, Rha	Gal, Man, Rib	Gal, Rha
Phospholipids[c]	PE, OH-PE, PI, PIM, DPG, PG (v)	PE, OH-PE, PI, PIM, DPG	PE	PE, DPG, PG, PI	PE
Predominant menaquinones	MK-9(H_4), MK-10(H_4)	MK-9(H_4), MK-9(H_6)	MK-9(H_4)	MK-9(H_4)	MK-9(H_4), trace MK-10(H_4)

[a]All genera have *meso*-diaminopimelic acid (A_2pm) as the cell-wall diamino acid, are of cell-wall chemotype III, and contain straight-chain, mono-unsaturated, iso, and anteiso fatty acids.

[b]Gal, Galactose; Man, mannose; Rib, ribose; Rha, rhamnose.

[c]DPG, Diphosphatidylglycerol; PE, phosphatidylethanolamine; PG, phosphatidylglycerol; PI, phosphatidylinositol; PIM, phosphatidylinositol mannosides; OH-PE, phosphatidylethanolamine containing hydroxylated fatty acids. v, Variable.

List of species of the genus *Saccharothrix*

1. **Saccharothrix australiensis** Labeda, Testa, Lechevalier and Lechevalier 1984, 430[VP]

aus.tra.li.en′sis. N.L. fem. adj. *australiensis* of or belonging to Australia, referring to the location of the soil sample from which the organism was first isolated.

Substrate mycelium is brownish to grayish-yellow in color. Sparse to abundant white to yellowish-gray aerial mycelium produced on many media. Brownish soluble pigments are formed on several media. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 76 (T_m).

Type strain: NRRL 11239, ATCC 31497, DSM 43800, IAM 14291, NBRC 14444, IMSNU 21246, JCM 3370, KCTC 9193, KCTC 9388, NCIMB 13188, VKM Ac-894, LL-BM782Ce82.

Sequence accession nos (16S rRNA gene): X53193.1, AF114803.

2. **Saccharothrix algeriensis** Zitouni, Lamari, Boudjella, Badji, Sabaou, Gaouar, Matthieu, Lebrihi and Labeda 2004, 1380[VP]

al.ge.ri.en′sis. N.L. fem. adj. *algeriensis* of Algeria, where the type strain originated.

Substrate mycelium is vivid yellow, orange-yellow, or yellowish-brown. Copious yellow-orange aerial mycelium is produced. A bright yellow soluble pigment is produced on some media. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: DSM 44581, JCM 13242, NRRL B-24137, SA 233.

Sequence accession no. (16S rRNA gene): AY054972.

3. **Saccharothrix coeruleofusca** (Preobrazhenskaya and Sveshnikova 1974) Grund and Kroppenstedt 1990a, 320[VP] (Effective publication: Grund and Kroppenstedt 1989, 270.) [*Actinomadura coeruleofusca* Preobrazhenskaya and Sveshnikova 1974, 864; *Nocardiopsis coeruleofusca* (Preobrazhenskaya and Sveshnikova 1974) Preobrazhenskaya and Sveshnikova 1985, 224]

co.e.ru.le.o.fus′ca. L. adj. *coeruleus* dark-colored, dark blue; L. adj. *fuscus* dark, swarthy, dusky, tawny; N.L. fem. adj. *coeruleofusca* blue-brown (referring to the color of aerial and substrate mycelium).

Substrate mycelium is yellowish in color. Only sparse aerial mycelia, if any, are produced on complex growth media. On glycerol-nitrate or starch-nitrate media, a blue to dark blue aerial mycelium is produced. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 67.0 (T_m) (Poschner et al., 1985).

Type strain: ATCC 35108, BCRC 13313, DSM 43679, IFO 14520, IMET 9602, IMSNU 21357, INA 1335, JCM 3313, KCTC 9389, NRRL B-16115, VKM Ac-855.

Sequence accession no. (16S rRNA gene): AF114805.

4. **Saccharothrix espanaensis** Labeda and Lechevalier 1989, 422[VP]

es.pa.na.en′sis. N.L. fem. adj. *espanaensis* of or belonging to Spain, referring to the source of the soil sample, Puerto Llano (Spain) from which the micro-organism was first isolated.

Substrate mycelium is grayish-yellow to yellowish-brown. Sparse white aerial mycelium is produced on some media, particularly glycerol-asparagine agar and inorganic salts-starch agar (ISP 3) and a yellow soluble pigment is also produced on these media. A brown to reddish-brown soluble pigment is formed on rich complex media. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 72.2 (T_m).

Type strain: ATCC 51144, CGMCC 4.1714, DSM 44229, IFO 15066, IMSNU 21342, JCM 9112, KCTC 9392, NBRC 15066, NRRL 15764, VKM Ac-1969.

Sequence accession no. (16S rRNA gene): AF114807.

5. **Saccharothrix longispora** (Preobrazhenskaya and Sveshnikova 1974) Grund and Kroppenstedt 1990a, 320[VP] (Effective publication: Grund and Kroppenstedt 1989, 272.) [*Actinomadura longispora* Preobrazhenskaya and Sveshnikova 1974, 866; *Nocardiopsis longispora* (Preobrazhenskaya and Sveshnikova 1974) Preobrazhenskaya and Sveshnikova 1985, 224]

lon.gi.spo′ra. L. adj. longus long; Gr. n. spora a seed and in biology a spore; N.L. n. *longispora* (nominative in apposition) the long spore, referring to the oblong shape of the spores.

Substrate mycelium has a yellow or red color and aerial mycelium is normally absent. On glycerol-nitrate agar a blue aerial mycelium is formed. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 68.0 (T_m) (Poschner et al., 1985).

Type strain: INA 10222, ATCC 35109, BCRC 13395, DSM 43749, HUT-6594, NBRC 14522, IMET 9603, IMSNU 21359, JCM 3314, KCTC 9394, NRRL B-16116, VKM Ac-907.

Sequence accession no. (16S rRNA gene): AF114809.

6. **Saccharothrix mutabilis** (Shearer, Colman and Nash 1983) Labeda and Lechevalier 1989, 422[VP] (*Nocardiopsis mutabilis* Shearer, Colman and Nash 1983, 374)

mu.ta′bi.lis. L. fem. adj. *mutabilis* changeable, variable, inconstant, referring to the variety of colony morphologies observed, particularly on rich organic media.

Substrate mycelium is yellow to yellowish-brown. White aerial mycelium is produced on most media. Upon exposure to light, the aerial mycelium may turn orange-yellow. Light yellow to yellowish-brown soluble pigments are produced on some media. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 73.1 (T_m).

Type strain: ATCC 31520, BCRC 12528, DSM 43853, IFM 240, NBRC 14310, IMSNU 21336, JCM 3380, KCTC 9397, NRRL B-16077, SKF AAA-025, VKM Ac-2023.

Sequence accession no. (16S rRNA gene): X76966.

This species has subsequently been divided into subspecies as follows.

6a. **Saccharothrix mutabilis subsp. mutabilis** (Shearer, Colman and Nash 1983) Labeda and Lechevalier 1989, 422[VP] (*Nocardiopsis mutabilis* Shearer, Colman and Nash 1983, 374)

Characteristics as above for *Saccharothrix mutabilis*.

6b. **Saccharothrix mutabilis subsp. capreolus** (*ex* Stark, Higgens, Wulfe, Hoehn and McGuire 1963) Grund and Kroppenstedt 1990a, 320[VP] (Effective publication: Grund and Kroppenstedt 1989, 273.) (*Streptomyces capreolus* Stark, Higgens, Wulfe, Hoehn and McGuire 1963, 596)

ca.pre′o.lus. L. masc. n. *capreolus* roebuck or chamois, two-pronged like the chamois, bifurcate.

Substrate mycelium is yellowish to brownish in color. Sparse, white aerial mycelium is produced on some media. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: ATCC 23892, BCRC 13692, CBS 678.68, DSM 40225, NBRC 12847, IMSNU 21351, ISP 5225, JCM 4248, JCM 4630, KCTC 9395, NCIMB 9611, NCIMB 9801, NRRL 2773, RIA 1167, VKM Ac-1848.

Sequence accession no. (16S rRNA gene): X76865.

7. **Saccharothrix syringae** (Gauze and Sveshnikova 1985) Grund and Kroppenstedt 1990a, 320[VP] (Effective publication: Grund and Kroppenstedt 1989, 273.) (*Nocardiopsis syringae* Gauze, Sveshnikova, Ukholina, Komarova and Bazhanov 1977, 483)

sy.rin′ga.e. N.L. fem. n. *Syringa* generic name of lilac; N.L. fem. gen. n. *syringae* of the lilac (referring to the color of aerial mycelium).

Substrate mycelium is yellowish to brownish in color. Aerial mycelium is sparse and white in color on most media. The aerial mycelium is reported (Gauze et al., 1977) to be pale to dark lilac in color on Gauze no. 1 mineral agar (Gauze et al., 1957) or glycerol-nitrate agar (Lindenbein, 1952), hence the species name. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): not determined.

Type strain: INA 2240, AS 4.1716, ATCC 51364, DSM 43886, NBRC 14523, IMET 9675, JCM 6844, KCTC 9398, NRRL B-16468, VKM Ac-1858.

Sequence accession no. (16S rRNA gene): AF114812.

8. **Saccharothrix texasensis** Labeda and Lyons 1989, 357[VP]

tex.as.en′sis. N.L. fem. adj. *texasensis* of or belonging to the state of Texas, referring to the source of the soil samples from which the species was first isolated.

Substrate mycelium is dark yellow to brownish-yellow. Sparse, white aerial mycelium is produced on some media. A brown to reddish-brown soluble pigment is formed on some media. Temperature for growth is 28°C.

Source: isolated from soil.

DNA G+C content (mol%): 74 (T_m).

Type strain: NRRL B-16134, AS 4.1713, ATCC 51593, DSM 44231, NBRC 14971, IMSNU 21343, JCM 9113, KCTC 9399, NCIMB 13186, VKM Ac-1968.

Sequence accession no. (16S rRNA gene): AF114814.

9. **Saccharothrix xinjiangensis** Hu, Zhou, Zhou, Liu and Liu 2004, 2094[VP]

xin.ji.ang.en′sis. N.L. fem. adj. *xinjiangensis* pertaining to Xinjiang, where the type strain was isolated.

The substrate mycelium is pinkish-buff in color on yeast extract-malt extract agar and pale orange to pale brown on other media. The aerial mycelium is grayish-white in color. Pale brown soluble pigments are produced on some media. Temperature for growth is 28°C.

Source: isolated from lake water.

DNA G+C content (mol%): 70.4 (T_m).

Type strain: AS 4.1731, DSM 44896, JCM 12329, NRRL B-24321, PYX-6.

Genus XVI. **Streptoalloteichus** Tomita, Nakakita, Hoshino, Numata and Kawaguchi 1987, 211[VP] emend. Tamura, Ishida, Otoguro, Hatano and Suzuki 2008b, 689

Seung Bum Kim and Tomohiko Tamura

Strep.to.al.lo.tei′chus. Gr. adj. *streptos* bent; Gr. adj. *allos* different; Gr. n. *teichos* wall; N.L. masc. n. *Streptoalloteichus* intended to mean streptomycete with different wall.

Gram-stain-positive, non-acid-fast, aerobic actinomycetes that show well-branched and non-fragmenting substrate hyphae. **Aerial mycelium bears chains of five to 50 spores** (0.5–1.2 µm wide) at the tip of well-branched hyphae. **Sporangia-like structures are formed**. The predominant menaquinones are **MK-9(H_6) and MK-10(H_6)**. The cell-wall peptidoglycan contains a major amount of ***meso*-diaminopimelic acid**. The predominant cellular fatty acids are **$C_{15:0}$ iso and $C_{17:0}$ anteiso**. Whole-cell hydrolysates contain **D-galactose and D-mannose**, whereas L-rhamnose and D-glucose are variably present. **Phosphatidylethanolamine** is present as the diagnostic phospholipid (phospholipid pattern type PII). Habitat: soil.

Type species: **Streptoalloteichus hindustanus** Tomita, Nakakita, Hoshino, Numata and Kawaguchi 1987, 211[VP].

Further descriptive information

The genus *Streptoalloteichus* currently belongs to the family *Pseudonocardiaceae* (Stackebrandt et al., 1997) and contains two species, *Streptoalloteichus hindustanus* and *Streptoalloteichus tenebrarius* (Table 259). However, the taxonomic affiliation of the genus at the family level looks rather unclear. *Streptoalloteichus*, together with *Crossiella* and *Kutzneria*, have been consistently placed outside both the *Pseudonocardiaceae* and *Actinosynnemataceae* clades, still residing within the former suborder *Pseudonocardineae* (Labeda, 2001; Labeda and Kroppenstedt, 2006), elevated in this volume to order *Pseudonocardiales*. Further phylogenetic studies on these genera and related taxa might be necessary to clarify their taxonomic positions within the order.

TABLE 259. Differential characteristics that distinguish the two species of the genus *Streptoalloteichus*[a]

Characteristic	*S. hindustanus* C677-91^T	*S. tenebrarius* NBRC 16177^T
Morphology:		
Sporangia-like vessels	+	–
Motile spores	+	–
Cell chemistry:		
Whole-cell sugars[b]	Gal, Man, Rha	Gal, Man, Glc
Menaquinones (MK-)	9(H_6), 10(H_6)	10(H_6), 10(H_4), 9(H_6), 9(H_4)
DNA G+C content (mol%)	nd	71.6
Cultural characteristics on inorganic salts-starch agar (ISP 4):		
Vegetative mycelium	Thin, colorless to grayish yellow	Grayish pink
Aerial mycelium	Pale pinkish yellow	Light grayish-yellow with white areas
Diffusible pigment	None	Grayish pink
Cultural characteristics on glycerol-asparagine agar (ISP 5):		
Growth	Restricted	Moderate
Vegetative mycelium	Thin, colorless to grayish yellow	Pale yellow
Aerial mycelium	Patches, white, turning yellowish gray later	Pale yellow with white areas
Cultural characteristics on Bennett's agar:		
Vegetative mycelium	Pale olivaceous yellow to light brown	Pale yellow
Aerial mycelium	Velvety, light yellowish beige	White
Utilization of:		
Maltose	–	+
L-Arabinose	–	+
D-Xylose	–	+
Salicin	–	+
myo-Inositol	–	+
Lactose	Weak	–
Antibiotic production	Tallysomycins A, B, and C; nebramycin factors II, IV′, and V′	Nebramycin factors I to XIII
Tolerance to 7% (w/v) NaCl[c]	–	+
Light sensitivity for formation of aerial mycelium	–	+

[a]Modified from Table 1 of Tamura et al. (2008b); nd, not determined.

[b]Gal, galactose; Man, mannose; Rha, rhamnose; Glc, glucose.

[c]Both grow at 5%, neither grows at 10%.

Streptoalloteichus hindustanus and *Streptoalloteichus tenebrarius* share 99.5% 16S rRNA gene sequence similarity, but only 24.3–37.9% DNA–DNA relatedness (Tamura et al., 2008b). The two species are clearly distinguishable by their morphological properties: *Streptoalloteichus hindustanus* produces oval or spherical sporangia-like vessels on the vegetative hyphae (Figure 332) and motile spores with a single polar flagellum. Sporangia-like structures can also be found, albeit with lower frequency, in *Streptoalloteichus tenebrarius* (Figure 333). However, the spores of *Streptoalloteichus tenebrarius* are nonmotile.

Purified cell wall preparations contain *meso*-diaminopimelic acid, but not the L-isomer or the hydroxy analogs. Alanine and glutamic acid are found in *Streptoalloteichus tenebrarius*. Whole-cell hydrolysates contain galactose and mannose; in addition, rhamnose and glucose are present in *Streptoalloteichus hindustanus* and *Streptoalloteichus tenebrarius*, respectively. The diagnostic phospholipid is phosphatidylethanolamine (phospholipid type PII). The predominant fatty acids of *Streptoalloteichus* are $C_{15:0}$ iso and $C_{17:0}$ anteiso.

Both species of *Streptoalloteichus* are known to produce nebramycins and *Streptoalloteichus hindustanus* is also known to produce tallysomycins.

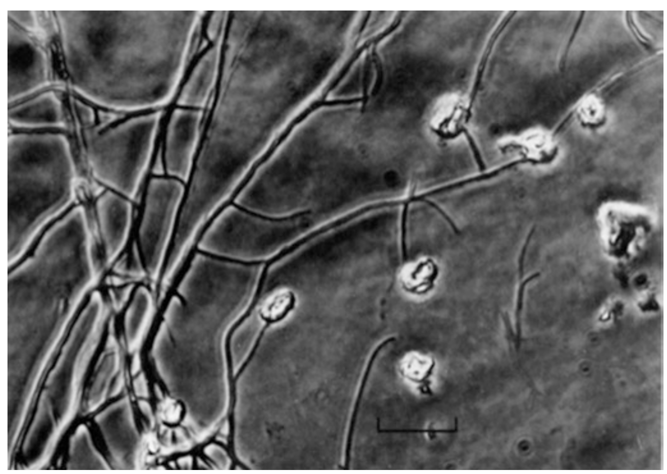

FIGURE 332. Sporangia-like vessels enveloping a single spore or a row of two to four spores of *Streptoalloteichus hindustanus*, which are formed on the sporangiophore of the substrate mycelium. Bar = 10 µm.

Enrichment and isolation procedures

Streptoalloteichus hindustanus was isolated from dry soil samples collected in Gujarat or adjacent states where the natural vegetation is dry tropical forest and scrub using nutrient agar supplemented with butirosin (50 µg/ml). Yeast extract-malt extract agar (ISP 2) or Bennett's agar, supplemented with kanamycin or gentamicin (10 µg/ml) and nystatin (100 µg/ml), can also be used. The agar plates are incubated for 1–2 weeks at 43°C. Colonies of *Streptoalloteichus hindustanus*

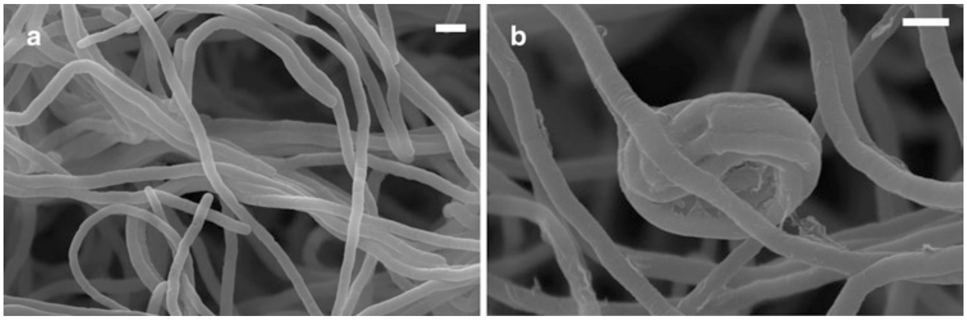

FIGURE 333. Scanning electron micrographic images of *Streptoalloteichus tenebrarius* showing the formation of arthrospore chains (a) and sporangia-like structure (b). Bars = 1 µm.

are distinguishable from those of most species of the genus *Streptomyces* by pale pinkish-yellow aerial mycelium, and the lack of a distinct reverse-side color.

Streptoalloteichus tenebrarius can be isolated from soil and grows on various media such as ISP 2, 4, and 5, and Bennett's agar medium.

Maintenance procedures

Streptoalloteichus strains can be maintained on media that is used universally for actinobacteria. The mixture of spores and mycelial fragments can be stored in 20% (v/v) glycerol solution at temperatures below −20°C or as lyophilized powder. Alternatively, the mixture is suspended in sterilized skim milk (10%) and stored at −80°C in screw-capped tubes. Lyophilization of the spore suspension is carried out by standard procedures for actinobacteria and the lyophilized culture is preserved under a vacuum of between 0.05 and 0.005 mmHg.

Procedures for testing special characters

Sporangia formation may be induced by growing the strains at 28°C for 3–4 weeks on ISP 2 or ISP 5 agar. Microscopic observation of sporangia and other structures in the vegetative mycelium can be achieved by preparing the cultures using the coverslip technique (Kawato and Shinobu, 1959).

Alternatively, ISP 5 broth or soil extract broth (Tomita, 1989) may be used. Media in metal-capped tubes (18×180 mm in size; 3 ml medium per tube) are autoclaved, inoculated heavily with a spore suspension, and incubated as slants for 4–6 weeks at 28°C. The sporangia can be observed at hyphal tips of mycelial masses.

Differentiation from closely related taxa

Streptoalloteichus is phylogenetically mostly related to members of the genera *Goodfellowiella*, *Crossiella*, and *Kibdelosporangium*, with 16S rRNA gene sequence similarities between strains of 95 to 96% (Figure 334). However, *Streptoalloteichus* can be differentiated from the other three genera based on chemotaxonomic properties. The major isoprenoid quinones of *Streptoalloteichus* are MK-9(H_6) and MK-10(H_6), whereas those of *Goodfellowiella* are MK-9(H_4) and MK-10(H_4), and that of *Crossiella* and *Kibdelosporangium* is MK-9(H_4). Mannose is one of the diagnostic sugars for *Streptoalloteichus*, but not for *Goodfellowiella* or *Kibdelosporangium*.

Streptoalloteichus can be distinguished from other genera of the family *Pseudonocardiaceae* by a combination of morphological and chemotaxonomic properties, such as spore chains, sporangia-like structures, phospholipid type, menaquinone profiles, and diagnostic sugars. In particular, the menaquinone profiles, consisting of MK-9(H_6) and MK-10(H_6), distinguish the genus from the rest of the family *Pseudonocardiaceae*. The presence of galactose and mannose in the cell wall also separates the genus from the genera *Actinoalloteichus*, *Actinopolyspora*, *Amycolatopsis*, *Goodfellowiella*, *Kibdelosporangium*, *Pseudonocardia*, *Prauserella*, *Saccharomonospora*, and *Saccharopolyspora*. The phospholipid pattern of *Streptoalloteichus* is type II *sensu* Lechevalier et al. (1977a), which is different from those of *Actinopolyspora* (type III), *Saccharopolyspora* (type III), and *Thermobispora* (type IV).

Formation of sporangia-like structures separates the genus from *Actinoalloteichus*, *Actinopolyspora*, *Goodfellowiella*, *Prauserella*, *Saccharopolyspora*, and *Thermobispora*. Mycelial fragmentation is not observed in *Streptoalloteichus*, which is different from *Actinoalloteichus*, *Amycolatopsis*, *Crossiella*, *Goodfellowiella*, *Kibdelosporangium*, *Prauserella*, *Saccharopolyspora*, and *Thermoscrispum*.

Streptoalloteichus can also be differentiated from related genera using 16S rRNA gene restriction fragment length polymorphism (RFLP) patterns, as suggested by Cook and Meyers (2003). All actinobacterial taxa can be divided into three distinct groups based on the RFLP patterns of 16S rRNA gene with *Sau*3A1. *Streptoalloteichus* belongs to Group 3; additional RFLP patterns with restriction enzymes *Asn*1 and *Sph*1 separate the genus from other genera of Group 3.

Taxonomic comments

The genus *Streptoalloteichus* with *Streptoalloteichus hindustanus* as the type and only species was formally published by Tomita et al. (1987), although the genus was originally proposed in 1978 (Tomita et al., 1978). *Streptoalloteichus tenebrarius* was originally described as "*Streptomyces tenebrarius*" (Higgins and Kastner, 1967). *Streptoalloteichus hindustanus* and *Streptoalloteichus tenebrarius* share a number of properties in common, e.g. cell-wall type, production of short spore chain clusters, smooth-surfaced spores, sclerotium formation, and pale pinkish-yellow aerial mycelium. On the other hand, the two species can be differentiated from each other based on various phenotypic characters. For example, the sporangia-like vessels enveloping motile spores are rarely observed in *Streptoalloteichus tenebrarius* and light sensitivity in the formation of aerial mycelium is only observed in *Streptoalloteichus tenebrarius*. Growth at 45°C has been reported for *Streptoalloteichus hindustanus*, but not for *Streptoalloteichus tenebrarius*. Similarly, *Streptoalloteichus tenebrarius* can grow in the presence of 7% NaCl, but *Streptoalloteichus hindustanus* cannot. The latter produces tallysomycins A, B, and C, and nebramycin factors II, IV′, and V′, whereas *Streptoalloteichus tenebrarius* produces nebramycin factors I to XIII.

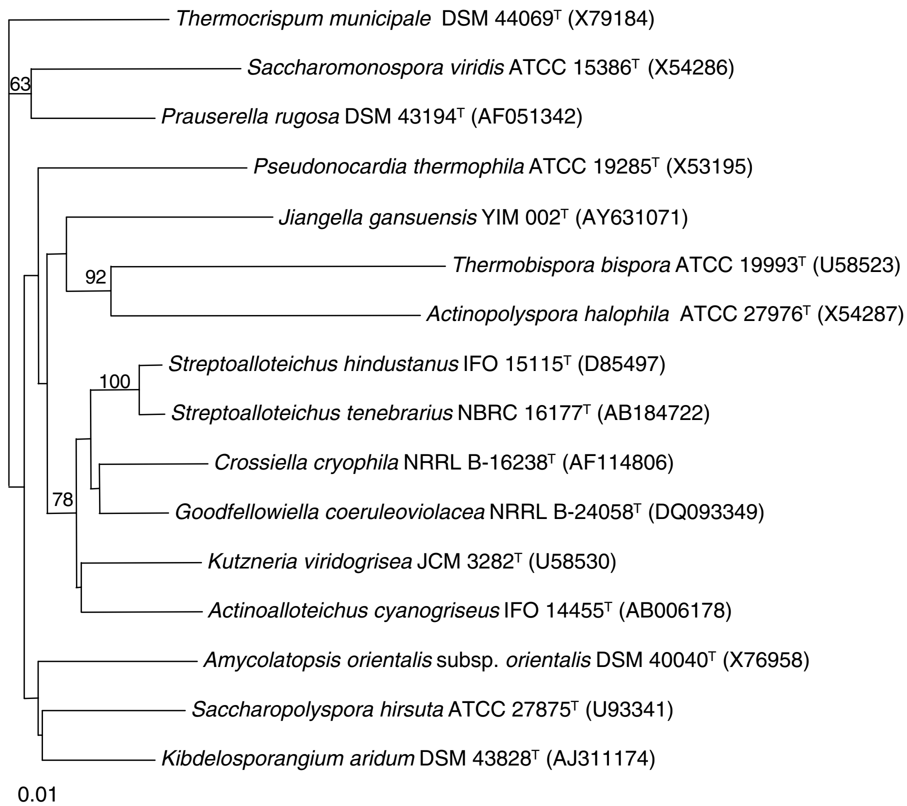

FIGURE 334. Phylogenetic tree of the genus *Streptoalloteichus* and related taxa based on 16S rRNA gene sequences. The Jukes–Cantor model was used in the estimation of evolutionary distances and the neighbor-joining method was used for tree construction. Numbers at nodes indicate levels of bootstrap support (%). Bar = 0.01 substitutions per nucleotide position.

Miscellaneous comments

Streptoalloteichus hindustanus has the ability to bear both non-motile conidiospores and motile sporangiospores. This morphology may be derived from adaptation to the original environments of this micro-organism, which have dry and rainy seasons in a year. *Streptoalloteichus hindustanus* was reported to produce tallysomycins A, B, and C, antitumor compounds, and BMY-28190, an antiviral agent (Ohkuma et al., 1988). *Streptoalloteichus* sp. 1454-19 was reported to produce siderophores IC202A, B, and C (Iijima et al., 1999a, 1999b). The bleomycin resistance (*ble*) gene from *Streptoalloteichus hindustanus* has been used as a dominant selection marker to construct transformation systems in animal, plant, fungal, and bacterial cells (Drocourt et al., 1990).

List of species of the genus *Streptoalloteichus*

1. **Streptoalloteichus hindustanus** Tomita, Nakakita, Hoshino, Numata and Kawaguchi 1987, 211[VP]

hin.du.stan′us. N.L. masc. adj. *hindustanus* of Hindustan, northwest region of India.

The aerial mycelium is abundant on most culture media. After sporulation, the aerial mycelium is pale in color and yellow, pink, or gray depending on the medium. The vegetative mycelium is colorless to light yellowish brown. Both substrate and aerial mycelia are well developed and branched, averaging 0.5 µm in diameter. Chains of spores are formed only at the tip of the aerial mycelium. These may be either long (10–50 spores in a chain) or short, hooked, branching spore chains. The individual arthrospores in the long chains are oval to cylindrical (0.5–2.0 µm in diameter) and the conidiospores in the short chains are barrel shaped. The spore surface is smooth in both cases. Spores are motile with a single polar flagellum. The spore chain cluster consists of curved or L-shaped conidiophore chains with many branches and often develops into a thick mass. The substrate mycelium does not fragment. The substrate mycelium penetrating the agar is thin, especially in chemically defined media; it is covered with a thick mass of white aerial mycelium that turns to pale yellow after sporulation. Single, oval, or spherical sporangia-like vessels enveloping one spore or a single row of two to four spores are randomly formed among the vegetative hyphae. Sporangia are 1.5–4.5 × 2.7–7.0 µm in size and sporangiospores are 0.9–1.5 × 1.2–4.0 µm. Globose dense bodies consisting of coalesced vegetative mycelium and sclerotia may be formed on the aerial mycelium. The temperature range for growth is 20–54°C; no growth is observed at 56°C. The optimal temperature for growth is 45°C. Additional cultural and physiological characteristics are shown in Table 260.

TABLE 260. Cultural characteristics of *Streptoalloteichus hindustanus*

Medium	Aerial mycelium	Vegetative mycelium	Diffusible pigments
Yeast extract-malt extract (ISP 2)	Thick pale yellowish pink	Light yellowish brown	None
Inorganic salts-starch (ISP 4)	Pale pinkish yellow	Thin, colorless to grayish yellow	None
Glycerol-asparagine (ISP 5)	Patches, white, turning yellowish gray later	Thin, colorless to grayish yellow	None
Peptone-yeast extract-iron (ISP 6)	Scant, white	Moderate brown	Light yellowish brown

Gelatin, casein, and starch are hydrolyzed; skim milk is coagulated and slightly peptonized. Melanoid pigments are not formed on ISP 1, 6, or 7. Catalase-positive, but tyrosinase-negative. Nitrate reduction occurs. Abundant growth is observed at 30–50°C, but no growth is seen at 56°C. Growth occurs with up to 5% (w/v) NaCl, but not with 7% (w/v). Utilizes D-fructose, D-galactose, D-glucose, and D-mannose as sole carbon sources, but not L-arabinose, inositol, D-mannitol, D-raffinose, L-rhamnose, D-sorbitol, or D-xylose. Weak growth occurs on lactose and sucrose. Resistant to ampicillin, cephalothin, erythromycin, gentamicin, kanamycin, and tetracycline at 100 µg/ml, and to novobiocin at 25 µg/ml. Less resistant to chloramphenicol and rifampin. Major menaquinones are MK-9(H_6) and MK-10(H_6).

Source: soil.

DNA G+C content (mol%): Not known.

Type strain: ATCC 31217, IFO 15115.

Sequence accession no. (16S rRNA gene): D85497.

2. **Streptoalloteichus tenebrarius** (*ex* Higgins and Kastner 1967) Tamura, Ishida, Otoguro, Hatano and Suzuki 2008b, 689[VP] (Subjective synonym: "*Streptomyces tenebrarius*" Higgins and Kastner 1967.)

te.ne.bra′ri.us. L. masc. adj. *tenebrarius* of or belonging to darkness, reflecting the sensitivity of the culture to light.

Straight spore chains are formed on short sporophores on the substrate mycelium. Spores have a smooth surface and are short, nonmotile rods (0.6–0.9 × 1.0–1.5 µm). Sporangia-like structures, though not common, can be formed. No soluble pigment is produced on ISP 7 agar medium.

Starch is hydrolyzed weakly and gelatin is hydrolyzed. Calcium malate is not decomposed and milk is not coagulated or peptonized. Optimum temperature for growth is 20–30°C; grows at 37°C, but not at 45°C. Grows in the presence of up to 8% (w/v) NaCl, but not in 10% (w/v) NaCl.

N-Acetyl-D-galactosamine, *N*-acetyl-D-glucosamine, arabonic acid, *p*-arbutin, D-fructose, gluconate, D-glucosamine, D-glucosaminic acid, D-glucose, glycogen, maltose, D-mannose, D-ribose, L-arabinose, D-xylose, sucrose, raffinose, salicin, starch, trehalose, adonitol, glycerol, *myo*-inositol, acetate, butyrate, caprate, isobutyrate, propionate, *cis*-aconitate, azelate, citrate, fumarate, DL-3-hydroxybutyrate, D-lactate, DL-lactate, DL-malate, L-malate, oxaloacetate, 2-oxoglutarate, pyruvate, acetamidocaprate, acetyl L-glutamine, acetyl glycine, D-alanine, β-alanine, L-arginine, L-asparagine, L-aspartate, casein, L-citrulline, L-glutamate, L-glutamine, L-histidine, L-isoleucine, L-leucine, L-ornithine, L-proline, L-serine, L-tryptophan, L-valine, and ethanolamine are utilized as sole carbon sources (as sodium salts where applicable). Major menaquinones are MK-10(H_6), MK-10(H_4), MK-9(H_6), and MK-9(H_4).

Source: soil.

DNA G+C content (mol%): 71.6 (HPLC)

Type strain: NBRC 16177, ATCC 17920, DSM 40477, JCM 4838, NRRL B-12390, ISP 5477.

Sequence accession no. (16S rRNA gene): AB184722.

Genus XVII. **Thermocrispum** Korn-Wendisch, Rainey, Kroppenstedt, Kempf, Majazza, Kutzner and Stackebrandt 1995, 73[VP]

Seung Bum Kim

Ther.mo.cris′pum. Gr. adj. *thermos* warm, hot; L. neut. adj. *crispum* tightly curled; N.L. neut. n. *Thermocrispum* a heat-loving, tightly curled organism.

Thermophilic, Gram-stain-positive, aerobic, catalase-positive, and non-acid-fast. Produces filamentous, branched hyphae. The **aerial mycelium is white**, and the **vegetative mycelium is yellow to light brown**. Soluble pigments are not produced. **Aerial hyphae are straight to flexuous and often aggregate into clusters (pseudosporangia) that fragment into rod-like structures**. Good growth occurs on Czapek Dox-yeast extract-Casamino acids (CYC) agar, glucose-yeast extract-malt extract (GYM) agar, Hickey–Tresner agar, oatmeal agar, potato-carrot agar, peptone-maize extract (PM) agar, R2A agar, and R8 agar, as well as on tryptic soy agar (TSA). **The temperature range for growth is 20–62.5°C**; the optimum range is 45–55°C. Growth occurs between pH 6.0 and 11.0, and also in the presence of NaCl (5%, w/v), novobiocin (25 µg/ml), and crystal violet (0.2 µg/ml). Nitrate is reduced to nitrite under aerobic conditions. The **cell wall contains *meso*-diaminopimelic acid and the whole-cell sugar pattern is type C**; **major amounts of arabinose, mannose, and glucose are present**, but only traces of galactose are detected. **Phospholipid pattern is type PII**, containing phosphatidylethanolamine as the diagnostic phospholipid. Mycolic acids are not present. The **predominant menaquinone is MK-9(H_4)**. Resistant to a set of phages that infect the genera *Amycolatopsis*, *Pseudonocardia*, *Saccharomonospora*, *Saccharopolyspora*, and *Saccharothrix*. Sensitive to genus-specific phages isolated from different habitats.

DNA G+C content (mol%): 69–73 (HPLC).

Type species: **Thermocrispum municipale** Korn-Wendisch, Rainey, Kroppenstedt, Kempf, Majazza, Kutzner and Stackebrandt 1995, 73[VP].

Further descriptive information

The genus *Thermocrispum* belongs to the family *Pseudonocardiaceae* and currently contains two species, *Thermocrispum agreste* and *Thermocrispum municipale* (Figure 335). The 16S rRNA gene sequence similarity between the type strains of the two species was reported as 98.2% (Korn-Wendisch et al., 1995), but BLAST (http://blast.ncbi.nlm.nih.gov/blast.cgi) results indicate a lower similarity value (96.0%).

Good growth of all *Thermocrispum* strains can be observed on the media mentioned in the genus description. Macroscopically, the isolates are similar to members of the genus *Saccharopolyspora*. All strains produce abundant white aerial mycelium and yellow to light brown substrate mycelium on CYC agar (Cross and Attwell, 1974) and potato-carrot agar (Cross et al., 1963), whereas sparse to moderate aerial mycelium is formed on TSA, GYM agar (ISP medium 4), oatmeal agar (ISP medium 3), PM agar (Agre, 1964), and R2A agar (Reasoner and Geldreich, 1985). Growth is poor on glycerol-arginine agar (El-Nakeeb and Lechevalier, 1963). The surfaces of colonies are covered with straight to flexuous aerial hyphae and both substrate and aerial mycelia often form aggregates (Figure 336). The aerial mycelium fragments into rod-like structures (Figure 337). Pseudosporangia similar to the structures of *Kibdelosporangium* can be observed in all strains. However, these structures are not surrounded by a well-defined wall and contain septate hyphae which fragment into rod-like structures (Figure 338).

Thermocrispum strains can degrade or hydrolyze casein, tyrosine, gelatin, DNA, esculin, Tween 80, and tributyrin, but not adenine, allantoin, cellulose, chitin, poly-β-hydroxybutyric acid, hypoxanthine, starch, urea, xanthine, or xylan. Pectin is weakly degraded and arbutin is hydrolyzed slowly. Melanoid pigments are not produced. Cellobiose, dextrin, galactose, glucose, inositol, mannose, sucrose, trehalose, sodium malonate, and sodium pyruvate are utilized as sole carbon sources, but adonitol, inulin, lactose, melibiose, raffinose, rhamnose, xylitol, xylose, and sodium propionate are not. Mannitol, melezitose, and sorbitol are utilized poorly.

All strains grow well at temperatures ranging from 28 to 60°C and between pH 6.0 and 11.0. Growth is weak at 20°C and inhibited at 65°C. All strains are resistant to novobiocin and crystal violet, and also to 5% (w/v) NaCl when the basal medium is GYM agar or TSA. All strains are susceptible to lysozyme degradation. *Thermocrispum* strains do not exhibit antibiotic activity against *Escherichia coli*, *Corynebacterium glutamicum*, *Bacillus subtilis*, or *Staphylococcus aureus*. The type strain of *Thermocrispum agreste* is slightly active against *Rhodococcus rhodochrous* and *Micrococcus luteus*, and also inhibits *Azotobacter chroococcum*, *Candida albicans*,

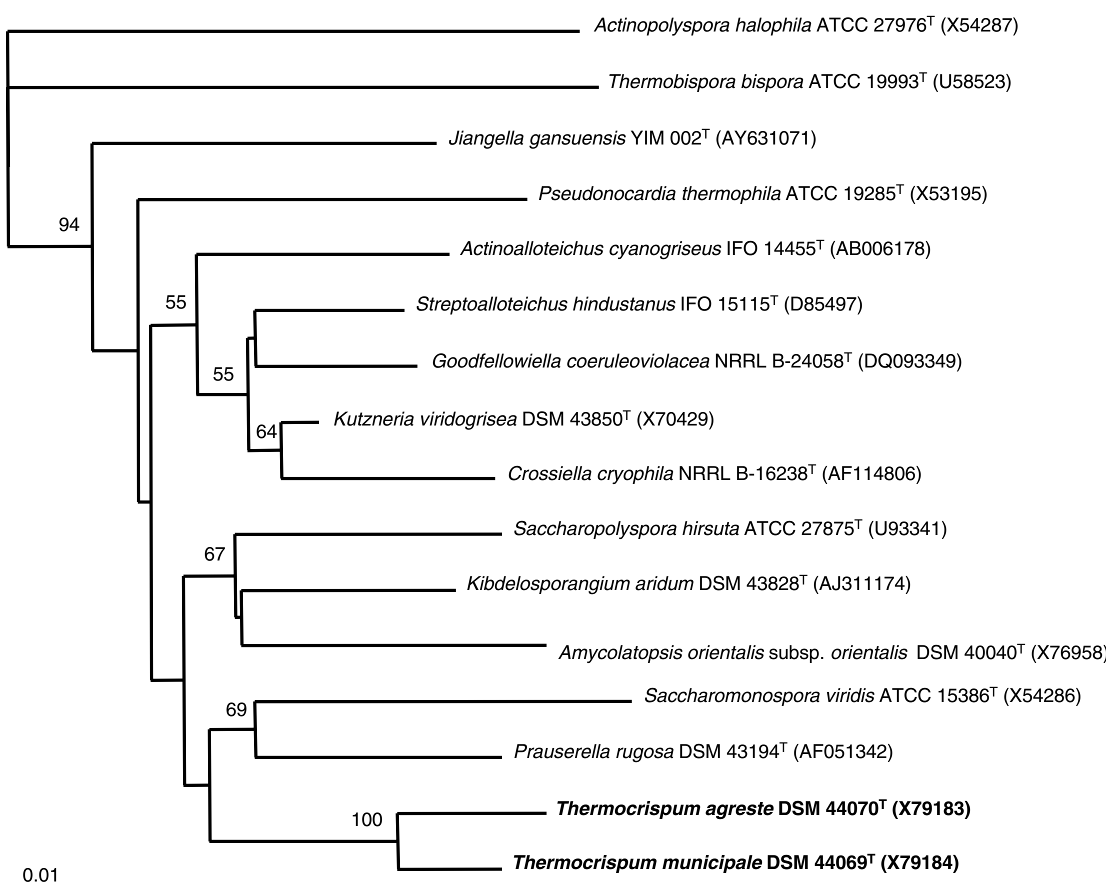

FIGURE 335. Phylogenetic tree of the genus *Thermocrispum* and related taxa based on 16S rRNA gene sequences. The Jukes–Cantor model was used in the estimation of evolutionary distances and the neighbor-joining method was used for tree construction. Numbers at nodes indicate levels of bootstrap support (%). Bar = 0.01 substitutions per nucleotide position.

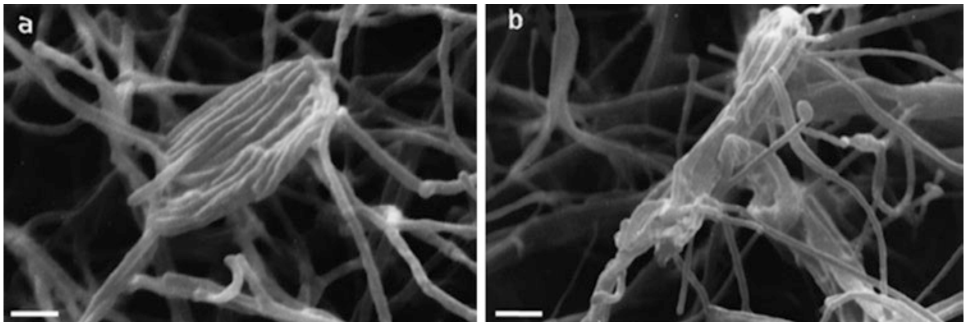

FIGURE 336. Scanning electron micrographic images of aerial mycelia of *Thermocrispum municipale* MKD35^T (a; bar = 1 μm) and *Thermocrispum agreste* CHB77^T (b; bar = 2 μm). (Reproduced with permission from Korn-Wendisch et al., 1995. Int. J. Syst. Bacteriol. *45*: 67–77.)

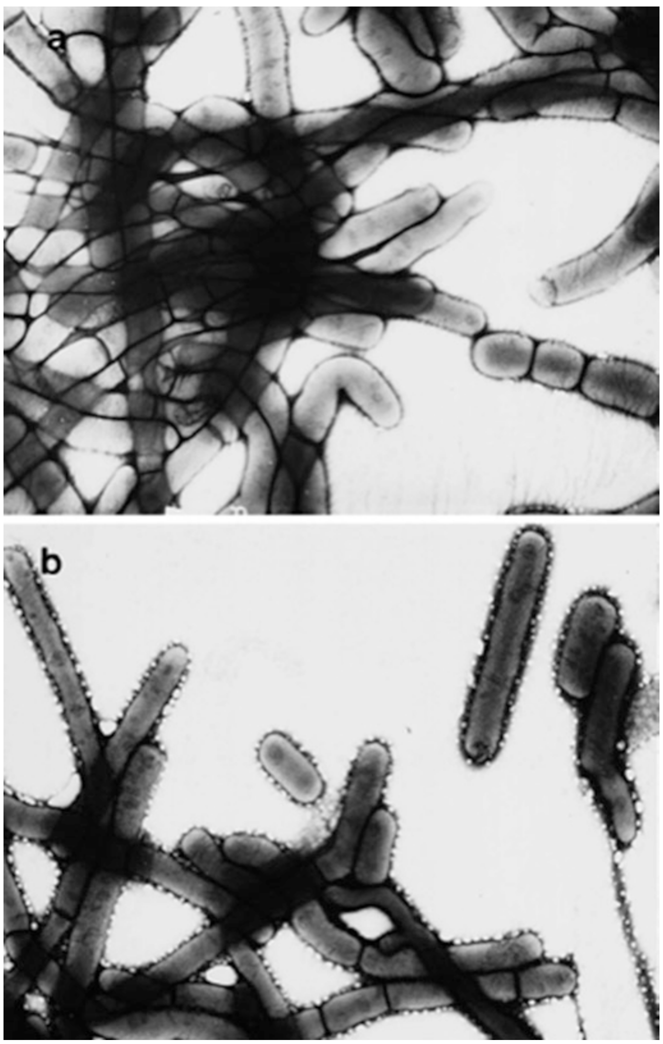

FIGURE 337. Transmission electron micrographic images of aerial mycelia of *Thermocrispum municipale* MKD35^T (a) and *Thermocrispum agreste* CHB77^T (b). Magnification 25,000×. (Reproduced with permission from Korn-Wendisch et al., 1995. Int. J. Syst. Bacteriol. *45*: 67–77.)

Saccharomyces cerevisiae, and *Geotrichum candidum*. A plasmid of about 35 kb was detected in *Thermocrispum municipale* MKD19.

All strains have similar phospholipid patterns and contain phosphatidylethanolamine, phosphatidylinositol, hydroxy-phosphatidylethanolamine, and an unknown ninhydrin-positive lipid (phospholipid type PII). This phospholipid pattern is also found in the genera *Saccharothrix* and *Kutzneria* and in some other genera of the family *Pseudonocardiaceae*, including the genera *Amycolatopsis*, *Kibdelosporangium*, and *Saccharomonospora*. MK-9(H_4) is the predominant menaquinone (95–100%) in all strains of *Thermocrispum* studied. The DNA G+C contents of *Thermocrispum* strains range from 69 to 70 mol%, except for *Thermocrispum municipale* MKD19 (73 mol%). All strains exhibit qualitatively similar fatty acid profiles consisting mainly of 14-methylpentadecanoic acid ($C_{16:0}$ iso) and 2-hydroxy fatty acids (fatty acid type 3f); iso-, anteiso-, and 10-methyl branched fatty acids with 17 carbons are found in smaller amounts.

On the basis of the typing results using actinophages, the two species of *Thermocrispum* can be separated from each other. *Thermocrispum agreste* CHB77^T can be lyzed by its corresponding phage, f77, but is sensitive to only two of the five phages isolated for *Thermocrispum municipale* strains MKD8, MKD10, MKD19, MKD35^T, and MKD38, even if high phage titers are used. In contrast, only four of the nine *Thermocrispum municipale* strains can be lyzed by a high titer of f77. The strains of *Thermocrispum municipale* form three subgroups; group 1, strains MKD8, TMK2, and TMD78, can be lyzed by all five phages isolated for strains MKD8, MKD10, MKD19, MKD35^T, and MKD38; group 2, strains TMS14 and MKD38, are not lyzed by f10 even if high phage titers are used, and strain MKD35^T can be lyzed by this phage only if a high phage titer is used; group 3, strains MKD10, MKD19, and MKD57, are sensitive to phages f35 and f38 only if high phage titers are used.

The band patterns of esterases were shown to differentiate *Thermocrispum agreste* from strains of *Thermocrispum municipale* (Korn-Wendisch et al., 1995).

Enrichment and isolation procedures

Strains of *Thermocrispum municipale* can be isolated from municipal waste compost, and air of compost plants and refuse incineration plants. *Thermocrispum agreste* can be isolated from mushroom compost. Isolation methods include the dilution plate technique for isolation from various environments and use of an Andersen sampler for collecting isolates from aerosols at waste-composting plants. Since the organisms are thermophilic, high temperatures such as 50°C are used for isolation. *Thermocrispum* strains have been found to grow on the following six media combinations: R8 agar and TSA without antibiotics, TSA supplemented with rifampin (10 mg/ml), TSA supplemented with erythromycin and oleandomycin (100 mg/ml each), TSA supplemented with novobiocin (25 mg/ml), and PM agar supplemented with

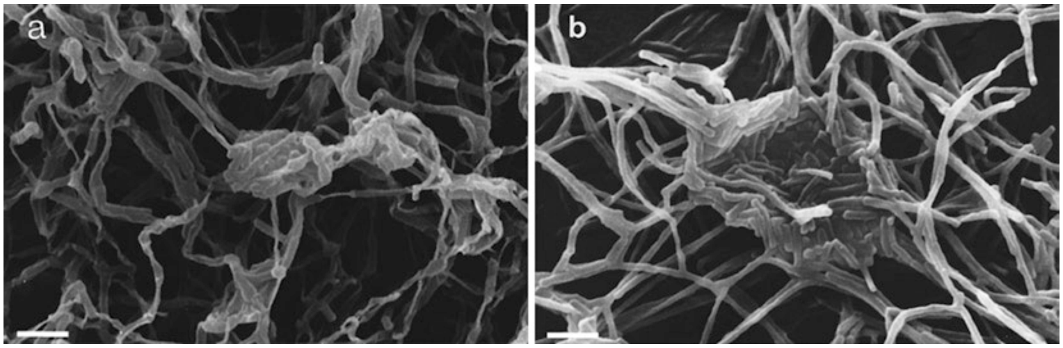

FIGURE 338. Scanning electron micrographic images of *Thermocrispum municipale* MKD35^T showing pseudosporangia (a) and a pseudosporangium containing septate hyphae which fragmented into rod-like structures (b). Bars = 1 μm. (Reproduced with permission from Korn-Wendisch et al., 1995. Int. J. Syst. Bacteriol. *45*: 67–77.)

novobiocin (25 mg/ml). To inhibit fungal growth, cycloheximide and nystatin (50 mg/ml each) are added to the media.

Maintenance procedures

Strains of *Thermocrispum* can be maintained on CYC agar, GYM agar, Hickey–Tresner agar (Hickey and Tresner, 1952), oatmeal agar, potato-carrot agar, PM agar, R2A agar, and R8 agar (Amner et al., 1989), and TSA. The optimum temperature for growth is between 45 and 55°C at neutral pH. For long-term preservation, storage of mycelial or spore suspensions in 20% (v/v) glycerol at −20°C, or lyophilization is recommended.

Differentiation of the genus *Thermocrispum* from closely related taxa

Thermocrispum can be differentiated from related genera of the family *Pseudonocardiaceae* based on chemotaxonomic profiles (Korn-Wendisch et al., 1995). The cell-wall chemotype of *Thermocrispum* (type III) is different from that of *Actinopolyspora*, *Amycolatopsis*, *Kibdelosporangium*, *Pseudonocardia*, *Saccharomonospora*, and *Saccharopolyspora* (type IV). The phospholipid pattern of *Thermocrispum* (PII) is different from that of *Actinopolyspora*, *Pseudonocardia*, and *Saccharopolyspora*. MK-8(H_4), found among *Pseudonocardia* and *Saccharomonospora*, is not present in *Thermocrispum*.

From the phylogenetic analysis, *Amycolatopsis*, *Kibdelosporangium*, *Prauserella*, *Saccharomonospora*, and *Saccharopolyspora* are shown as the neighboring genera (Figure 335), but the levels of 16S rRNA gene sequence similarity between the species of *Thermocrispum* and the type species of these taxa are below 94.4% based on BLAST results (http://blast.ncbi.nlm.nih.gov/blast.cgi). *Thermocrispum* can also be differentiated from related genera using 16S rRNA gene restriction fragment patterns, as suggested by Cook and Meyers (2003).

Taxonomic comments

A recent report suggested that *Sciscionella marina* is loosely associated with *Thermocrispum municipale* sharing 93% sequence similarity (Tian et al., 2009); however, BLAST results indicate that the similarity level should be lower (91.9%). Since the initial description of the genus in 1995, no additional species have been described. The differences in phage sensitivity and fatty acid profiles among the strains of *Thermocrispum municipale* imply possible heterogeneity within the species (Korn-Wendisch et al., 1995). However, the 16S rRNA gene sequences of only two strains, including the type strain, are publicly available to date, and thus the phylogenetic relationship among the isolates is not clear. Further work on the isolates may be able to clarify the taxonomic positions of the *Thermocrispum municipale* strains.

TABLE 261. Differential characteristics of the two species of the genus *Thermocrispum*[a]

Properties	*T. municipale*	*T. agreste*
Growth at:		
20°C	w	tr
28°C	+++	++
62.5°C	(+)	++
65°C	−	−
Growth in the presence of NaCl at:		
7%	+++	++
10%	++	−
13%	−	−
Resistance to 25 μg/ml kanamycin	(+)	+
Degradation of:		
Elastin	−	+
Guanine	(+)	−
Utilization of:		
Fructose	+	tr
Maltose	+	(+)
Melezitose	v	tr
Mannitol	(+)	tr
Sorbitol (=glucitol)	v	tr
Salicin	(+)	+
Sodium acetate	+	tr
Sodium citrate	v	−
Hemolysis	−	+
Egg yolk reaction	−	+

[a]Data taken from Korn-Wendisch et al. (1995). Symbols: +++, good growth with abundant aerial mycelium; ++, good growth with moderate aerial mycelium; +, positive growth or reaction; (+), poor growth or moderate reaction; −, negative; w, weak; v, variable; tr, traces of growth.

Differentiation of the species of the genus *Thermocrispum*

Thermocrispum species can be distinguished from one another by using a combination of nutritional and physiological characteristics (Table 261).

List of species of the genus *Thermocrispum*

1. **Thermocrispum municipale** Korn-Wendisch, Rainey, Kroppenstedt, Kempf, Majazza, Kutzner and Stackebrandt 1995, 73[VP]

mu.ni.ci.pa′le. L. neut. adj. *municipale* municipal, referring to the environment from which strains were isolated.

White aerial mycelium with long, straight, or flexuous chains of spores are formed. Aerial mycelia fragment into rod-like structures and both aerial and substrate mycelia often form aggregates. Sporangia-like structures are formed. Good growth occurs between 28 and 60°C, but weak growth is observed at 20 and 62.5°C. No growth occurs at 65°C. Good growth is also observed in the presence of up to 10% (w/v) NaCl, but not at 13%. Moderately resistant to kanamycin (25 μg/ml). Casein, DNA, esculin, gelatin, tributyrin, Tween 80, and tyrosine are degraded or hydrolyzed. Guanine is moderately degraded, pectin is weakly degraded, and arbutin is slowly hydrolyzed. In contrast, adenine, allantoin, cellulose, chitin, elastin, hypoxanthine, poly-β-hydroxybutyric acid, starch, urea, xanthine, and xylan are not degraded or hydrolyzed. Melanin is not produced. Dextrin, fructose, glucose, galactose, inositol, maltose, mannose, cellobiose, sucrose, trehalose, sodium acetate, sodium malonate, and sodium pyruvate are utilized as sole carbon sources, and mannitol and salicin are utilized weakly. In contrast, adonitol, inulin, lactose, melibiose, oxalate, raffinose, rhamnose, xylitol, xylose, and sodium propionate are not utilized as sole carbon sources. Melezitose, sorbitol, and sodium citrate may or may not be utilized as sole carbon sources. Hemolysis and egg yolk reaction are negative. Nitrate is reduced to form nitrite under aerobic conditions. Resistant to novobiocin and crystal violet.

Source: municipal waste compost, air of compost plants, and air of a refuse incineration plant.

DNA G+C content (mol%): 69–73 (HPLC).

Type strain: MKD35, DSM 44069.

Sequence accession no. (16S rRNA gene): X79184.

2. **Thermocrispum agreste** Korn-Wendisch, Rainey, Kroppenstedt, Kempf, Majazza, Kutzner and Stackebrandt 1995, 73[VP]

a.gre′ste. L. neut. adj. *agreste* rural, referring to the origin of the compost from which the organism was isolated.

White aerial mycelium with long, straight, or flexuous chains of spores are formed. Aerial mycelia fragment into rod-like structures and both aerial and substrate mycelia often form aggregates. Sporangia-like structures are formed. Good growth occurs between 28 and 62.5°C; traces of growth are observed at 20°C, but not at 65°C. Good growth is also observed in the presence of up to 7% (w/v) NaCl, but not at 10%. Resistant to kanamycin (25 μg/ml). Casein, DNA, elastin, esculin, gelatin, tributyrin, Tween 80, and tyrosine are degraded or hydrolyzed. In contrast, adenine, allantoin, cellulose, chitin, guanine, hypoxanthine, poly-β-hydroxybutyric acid, starch, urea, xanthine, and xylan are not degraded or hydrolyzed. Melanin is not produced. Cellobiose, dextrin, glucose, galactose, inositol, mannose, salicin, sucrose, trehalose, sodium malonate, and sodium pyruvate are utilized as sole carbon sources, and maltose is utilized weakly. In contrast, adonitol, inulin, lactose, melibiose, oxalate, raffinose, rhamnose, xylitol, xylose, sodium citrate, and sodium propionate are not utilized as sole carbon sources. Only traces of growth occur in the presence of fructose, melezitose, mannitol, sorbitol, and sodium acetate as sole carbon sources. Hemolytic activity and egg yolk reactions are positive. Nitrate is reduced to form nitrite under aerobic conditions. Resistant to novobiocin and crystal violet. Inhibits growth of *Azotobacter chroococcum*, *Candida albicans*, *Saccharomyces cerevisiae*, and *Geotrichum candidum*, whereas slightly antagonistic against the Gram-stain-positive bacteria *Rhodococcus rhodochrous*, and *Micrococcus luteus*. No antagonistic activity is observed against *Escherichia coli*, *Corynebacterium glutamicum*, *Bacillus subtilis*, or *Staphylococcus aureus*.

Source: mushroom compost.

DNA G+C content (mol%): unknown.

Type strain: CHB77, DSM 44070.

Sequence accession no. (16S rRNA gene): X79183.

Genus XVIII. **Umezawaea** Labeda and Kroppenstedt 2007, 2761[VP]

David P. Labeda

Um.e.za.wa′e.a. N.L. fem. n. *Umezawaea* named for Hamao Umezawa (1914–1986), of the Institute of Microbial Chemistry, Tokyo, in recognition of his leadership and contributions to the study of the biology and natural products of actinomycetes.

Aerobic. Gram-stain-positive, non-acidfast, nonmotile actinomycetes. Branched substrate mycelium (approx. 0.3–0.5 μm in diameter) is produced; aerial mycelia are formed on some media. **Ovoid or cylindrical conidia (0.3–0.5 × 1.1–1.9 μm) are produced by fragmentation of substrate mycelium. Pseudosporangia are produced on some media. Contains *meso*-diaminopimelic acid as the diamino acid. The muramic acid in the cell-wall peptidoglycan is acetylated. The whole-cell sugar pattern consists of galactose, mannose, and ribose, with a trace of rhamnose. The phospholipid pattern consists predominantly of phosphatidylethanolamine, phosphatidylinositol, phosphatidylethanolamine containing hydoxylated fatty acids, and *lyso*-phosphatidylethanolamine. The predominant menaquinone is MK-9(H_4), with a trace of MK-10(H_4).** Mycolic acids are absent. Has a fatty acid profile consisting predominantly of $C_{16:0}$ iso fatty acids, with $C_{14:0}$ iso, $C_{15:0}$ iso, $C_{16:0}$, $C_{16:1}$, $C_{17:1}$, and $C_{16:1}$ iso as minor components. Phylogenetically, nearest neighbor is the genus *Saccharothrix*.

DNA G+C content (mol%): 74 (HPLC).

Type species: **Umezawaea tangerina** (Kinoshita, Igarashi, Ikeno, Hori and Hamada 2000) Labeda and Kroppenstedt 2007, 2761[VP].

Further descriptive information

Umezawaea tangerina was originally described as a species of the genus *Saccharothrix* (Kinoshita et al., 1999), although the production of pseudosporangia on the aerial mycelium, a feature not detected in other species in this genus, was noted. Phylogenetic analysis of species of the genus *Saccharothrix* and related genera revealed that *Saccharothrix tangerinus* consistently appeared distant from *Saccharothrix sensu stricto* (see Figure 290). A subsequent re-evaluation of the chemotaxonomic characteristics of this strain determined that it was different from the other taxa in the family *Pseudonocardiaceae*, particularly in regard to the presence of significant quantities of *lyso*-phosphatidylethanolamine in the phospholipid profile (Table 262). The nucleotide signatures in the 16S rRNA gene of *Umezawaea tangerina* are also different from those of *Saccharothrix* and related taxa (see Figure 309).

Enrichment and isolation procedures

Strains of *Lechevalieria*, *Lentzea*, and *Saccharothrix* have been isolated from soil samples by spread-plating serial soil dilutions onto routine selective media (such as 1.5% crude agar and 0.4% casein hydrolysate in tap water) used for the general isolation of actinomycetes. Shearer (1987) reported the use of typical actinomycete isolation media, such as Gauze mineral medium no. 1 (Gauze et al., 1957) or starch-casein agar (Küster and Williams, 1964), supplemented with 5–10 µg/ml penicillin G and 15 µg/ml nalidixic acid antibiotics to selectively isolate *Saccharothrix* strains that are phylogenetically close to *Umezawaea*.

Maintenance procedures

Working cultures of *Umezawaea* can be maintained as refrigerated (4°C) agar slants on an appropriate medium such as yeast extract-malt extract medium (Shirling and Gottlieb, 1966) or NZamine medium (DSMZ medium 554; DSMZ, 2001). The slants are generally incubated for 5–7 d at 28–30°C prior to refrigeration and then should be subcultured at monthly intervals. Longer term preservation of strains is best accomplished as frozen stocks in 20% aqueous glycerol at −80°C (mechanical freezer) to −172°C (liquid nitrogen vapor phase) or by using traditional lyophilization techniques.

Procedures for testing special characters

Strains are routinely cultivated on NZamine medium (DSMZ medium 554) at 28°C. Morphological observations are made on the media of Shirling and Gottlieb (1966) and NZamine medium.

Chemotaxonomic analyses of strains for whole-cell sugars, polar lipids, menaquinones, and fatty acids are performed using methods described previously by Saddler et al. (1991), Grund and Kroppenstedt (1990b), Minnikin et al. (1984), and Sasser (1990).

Physiological tests, including production of acid from carbohydrates, utilization of organic acids, and hydrolysis and decomposition of adenine, casein, esculin, hippurate, guanine, hypoxanthine, tyrosine, urea, and xanthine, are typically evaluated using the media of Gordon et al. (1974). Phosphatase activity is evaluated by using the method of Kurup and Schmitt (1973) substituting NZamine agar as the basal medium. Temperature range for growth is determined on slants of DSMZ medium 554 and salt tolerance on slants of the same medium supplemented with 4% and 5% NaCl.

Differentiation of the genus *Umezawaea* from other genera

Umezawaea strains can easily be differentiated from morphologically similar members of the suborder *Pseudonocardineae* by the presence of *lyso*-phosphatidylethanolamine as a predominant component in the polar lipid profiles in addition to phosphatidylethanolamine containing 2-hydroxy fatty acids (Table 262). The nucleotide signatures in the 16S rRNA gene sequences can be used to differentiate *Umezawaea* strains from *Saccharothrix* and other closely related genera in the family *Pseudonocardiaceae* (see Figure 309).

List of species of the genus *Umezawaea*

1. **Umezawaea tangerina** (Kinoshita, Igarashi, Ikeno, Hori and Hamada 2000) Labeda and Kroppenstedt 2007, 2761[VP] (*Saccharothrix tangerinus* Kinoshita, Igarashi, Ikeno, Hori and Hamada 2000, 949; effective publication: Kinoshita, Igarashi, Ikeno, Hori and Hamada 1999, 27.)

   tan.ger.i′na. N.L. fem. adj. *tangerina* tangerine-colored, referring to the color of the vegetative growth.

   The pale yellow, pale yellow-orange, or pale yellowish-brown substrate mycelium fragments into coccoidal-rod elements. White to brownish-white aerial mycelia are produced on some media and fragment into coccoid to coccoidal-rod elements. Pseudosporangia are sometimes produced on the aerial mycelia. Soluble pigments are faint brown or not produced. Melanin pigments are not produced. L-Arabinose, D-xylose, D-glucose, D-fructose, and inositol are utilized as sole carbon sources. Casein, hypoxanthine, starch, and tyrosine are hydrolyzed; adenine and urea are not hydrolyzed. Acid is produced from L-arabinose, cellobiose, dextrin, D-glucose, glycerol, and inositol, but not from adonitol or *meso*-erythritol. Citrate and oxalate are assimilated, but not DL-tartrate. Nitrate is not reduced. Phosphatase is produced. Grows in the presence of 4% (w/v) NaCl. Temperature range for growth is 20–30°C. Produces the antibiotic formamicin. Grows at 28°C.

   Source: isolated from soil.

   DNA G+C content (mol%): 74 (HPLC).

   Type strain: MK27-91F2, DSM 44720, FERM P-16053, JCM 10302, NBRC 16184, NRRL B-24463.

   Sequence accession no. (16S rRNA gene): AB020031.

TABLE 262. Chemotaxonomic characteristics of *Umezawaea* compared to other similar members of the family *Pseudonocardiaceae*[a]

Characteristic[b]	*Umezawaea*	*Actinokineospora*	*Actinosynnema*	*Crossiella*	*Goodfellowiella*	*Lechevalieria*	*Lentzea*	*Saccharothrix*
Whole-cell sugar pattern[c]	Gal, Man, Rib, Rha (tr)	Gal, Man, Rha	Gal, Man	Gal, Rha, Rib	Gal, Rib	Gal, Man, Rha	Gal, Man, Rib	Gal, Rha, Man (tr)
Phospholipids[d]	PE, PI, OH-PE, *lyso*-PE, DPG, DPG, PIM	PE	PE, OH-PE, PI, PIM, DPG	PE, DPG, PI, PIM, PME	PE, OH-PE, DPG	PE	PE, DPG, PG, PI	PE, OH-PE, PI, PIM, DPG, PG (v)

Strep.to.my.ce.ta.ce′a.e. N.L. masc. n. *Streptomyces* type genus of the family; L. suff. *-aceae* ending to denote a family; N.L. fem. pl. n. *Streptomycetaceae* the *Streptomyces* family.

Aerobic, Gram-stain-positive, non-acid–alcohol-fast actinomycetes that form an extensively branched substrate mycelium which rarely fragments. At maturity, the **aerial mycelium forms chains of three to many spores**. Members of a few species bear short chains of spores on the substrate mycelium. The organisms produce a **wide range of pigments**, which are responsible for the colors of the substrate and aerial mycelia. The organisms grow within different pH ranges and are chemo-organotrophic with an oxidative type of metabolism. **Walls of cells from the substrate mycelium contain either LL- or *meso*-diaminopimelic acid (A_2pm) as the predominant diamino acid; aerial or submerged spores contain LL-A_2pm (peptidoglycan type A3γ)**. Whole-organism **sugar profiles may contain major amounts of either galactose or galactose and rhamnose. Lipid profiles typically contain: hexa- and octahydrogenated menaquinones with nine isoprene units as the predominant isoprenologs; diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides as major polar lipids; and complex mixtures of saturated, and iso- and anteiso-fatty acids. Mycolic acids are not present**. The pattern of 16S rRNA gene sequence signatures consists of nucleotides at positions: 127:234 (G–C), 449 (A), 672:734 (C–G), 950:1231 (U–G), 952:1229 (U–A), 955:1225 (C–G), 965 (C), 986:1219 (A–U), and 1362 (C). The family *Streptomycetaceae* belongs to the order *Streptomycetales*.

DNA G+C content (mol%): generally 66–74.

Type genus: **Streptomyces** Waksman and Henrici 1943, 339^AL^.

Taxonomic comments

The family *Streptomycetaceae* was established in 1943 by Waksman and Henrici to accommodate actinomycetes with branched slender mycelia, rarely or not septate, spores on aerial hyphae, and not fragmenting into oidia (Waksman and Henrici, 1943). At that time, the description was mainly based on morphology. In the 8th edition of *Bergey's Manual of Determinative Bacteriology*, Pridham and Tresner (1974b) listed *Streptomyces*, *Streptoverticillium*, *Sporichthya*, and *Microellobosporia* as members of the family. Over the years, additional genera, like *Actinopycnidium*, *Actinosporangium*, *Chainia*, *Elytrosporangium*, *Kitasatoa*, and *Microellobosporia*, have been distinguished from *Streptomyces* by morphological criteria, but they have many phenotypic and genotypic characters in common with *Streptomyces* and have therefore been proposed as synonyms of this genus (Goodfellow et al., 1986a, 1986b, 1986c, 1986d, 1986e). The genus *Sporichthya* is now classified in the family *Sporichthyaceae* of the order *Frankiales* (Stackebrandt et al., 1997).

The genus *Streptoverticillium* was found to be distinguishable from *Streptomyces* by its verticillate sporophores, but also shared many characteristics with streptomycetes; numerical phenetic

(Kämpfer et al., 1991; Williams et al., 1983a) and rRNA–DNA similarities (Gladek et al., 1985; Witt and Stackebrandt, 1990) supported the proposal that the genus was a synonym of *Streptomyces* (Witt and Stackebrandt, 1990). Wellington et al. (1992) proposed the unification of *Kitasatospora* with *Streptomyces* on the basis of chemotaxonomic, biochemical, and 16S rRNA gene sequence similarities. However, Zhang et al. (1997) revived the genus mainly on the basis of the ratio of *meso*-A_2pm to LL-A_2pm in whole-cell hydrolysates. The *meso*-A_2pm content is 49–89% in *Kitasatospora* strains and 1–16% in *Streptomyces* strains. Furthermore, galactose is present in the whole-cell hydrolysates of *Kitasatospora* strains, but not in whole-cell hydrolysates of *Streptomyces* strains.

Kim et al. (2003b) proposed an additional member of the family, the genus *Streptacidiphilus*, which contained acidophilic actinomycetes isolated from acidic soils and litter. These actinomycetes grow over a pH range of 3.5–6.5, with optimum growth at pH 4.5–5.5.

The genera *Streptomyces*, *Kitasatospora*, and *Streptacidiphilus* are very difficult to differentiate on the basis of phenotypic features (including the few distinguishing chemotaxonomic markers given above). The few characteristic differentiating features are shown in Table 263. Although 16S rRNA gene sequence analyses have provided a framework for prokaryotic classification, the current classification based on this molecule has not clarified the taxonomic problems within the family *Streptomycetaceae* (Kämpfer, 2006). *Kitasatospora* and *Streptacidiphilus* form stable, separate sub-branches on the basis of phylogenetic analyses within the family *Streptomycetaceae*, but they are grouped within the large *Streptomyces* tree (Figure 339) and 16S rRNA gene sequence similarities are equally high to many *Streptomyces* species/groups and *Streptacidiphilus* species. On the basis of DNA–DNA microarray hybridizations, Hsiao and Kirby (2008) compared the genome content of *Streptomyces avermitilis*, "*Streptomyces cattleya*", "*Streptomyces maritimus*", and *Kitasatospora* (*Streptomyces*) *aureofaciens* with that of *Streptomyces coelicolor* A3(2) and found a very high agreement with the genome sequence data for *Streptomyces* and *Kitasatospora*.

For all these reasons, it is questionable whether a separate generic status for *Kitasatospora* and *Streptacidiphilus* is justified. In this edition of *Bergey's Manual*, these genera are cited as genera *incertae sedis*.

TABLE 263. Chemotaxonomic, morphological and physiological characteristics of *Kitasatospora*, *Streptacidiphilus*, and *Streptomyces* strains (according to Kim et al., 2003b)[a]

	Streptomyces	*Kitasatospora*	*Streptacidiphilus*
Long chains of spores formed on aerial hyphae	+	+	+
Optimal pH range	6.5–8.0[b]	nd	4.5–5.5
pH range for growth	5.0–11.5	5.5–9.0	3.5–6.0
A_2pm isomer(s) in whole-organism hydrolysates	LL-A_2pm	LL- and *meso*-A_2pm[c]	LL-A_2pm
Diagnostic sugars in whole-organism hydrolysates	None	Galactose[d]	Galactose, rhamnose
Predominant phospholipids[e]	DPG, PE, PI, PIMs	DPG, PE, PI, PIMs	DPG, PE, PI, PIMs
Major menaquiones[f]	MK-9(H_6,H_8)	MK-9(H_6,H_8)	MK-9(H_6,H_8)
Fatty acid pattern[g]	2c	2c	2c
DNA G+C content (mol%)	66–73	70–74	70–72

[a]Data taken from this and previous studies (Antony-Babu and Goodfellow, 2008; Lonsdale, 1985; Nakagaito et al., 1992a, 1992b; Ōmura et al., 1989; Shirling and Gottlieb, 1977; Williams et al., 1989).

[b]Alkaliphilic strains, which grow between pH 5.0 and 11.0, have an optimum at pH 9–9.5 (Mikami et al., 1982; Antony-Babu and Goodfellow, 2008).

[c]Aerial and submerged spores contain LL-A_2pm and vegetative mycelia *meso*-A_2pm.

[d]Rhamnose was detected in whole-organism hydrolysates of *Kitasatospora mediocidica* (Labeda, 1988).

[e]DPG, Diphosphatidylglycerol; PE, phosphatidylethanolamine; PI, phosphatidylinositol; PIMs, phosphatidylinositol mannosides.

[f]MK-9(H_6,H_8), hexa-and octa-hydrogenated menaquinones with nine isoprene units.

[g]Fatty acid group *sensu* Kroppenstedt (1985).

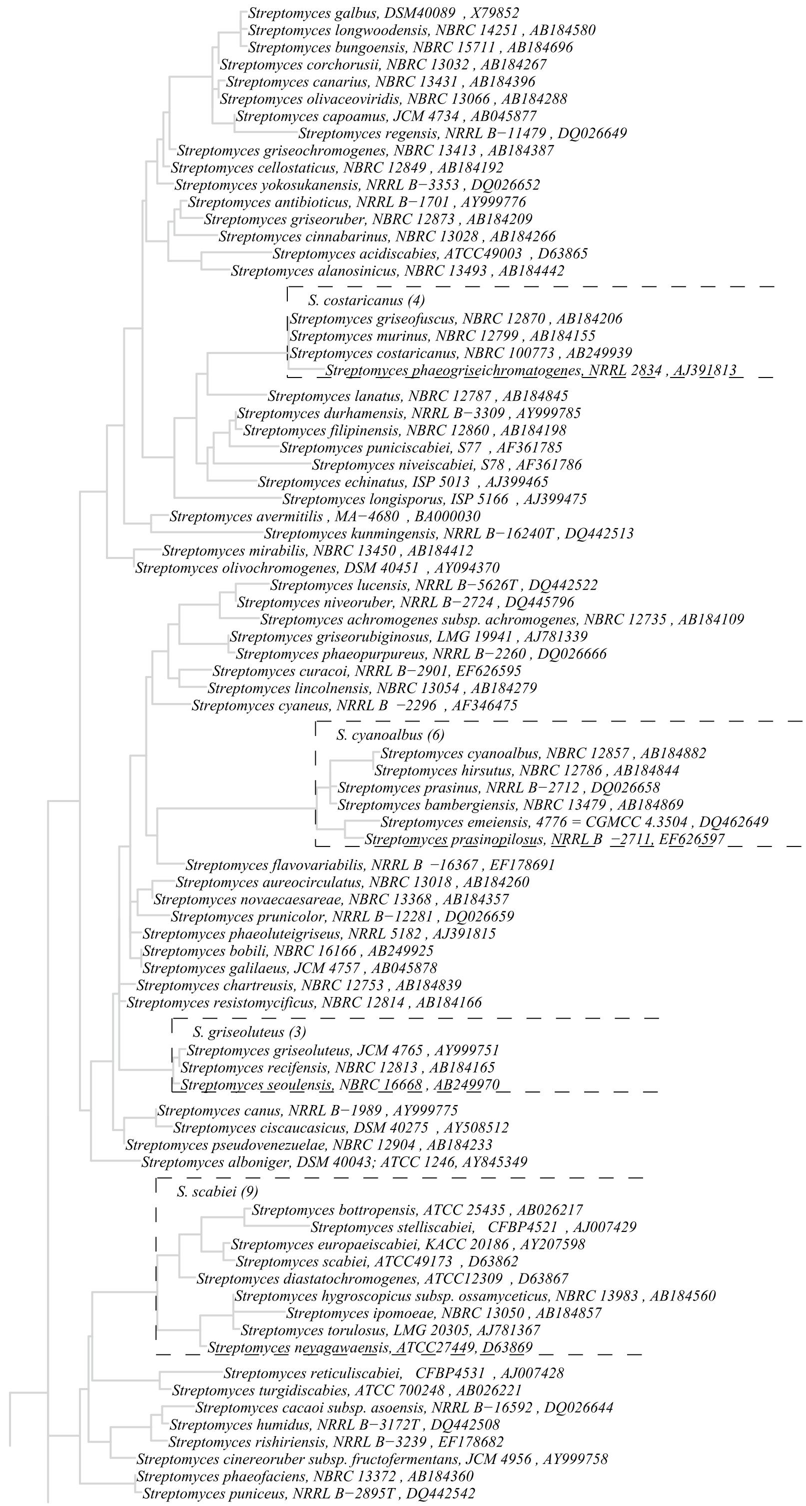

FIGURE 339. Phylogenetic analysis based on 16S rRNA gene sequences available from the EMBL database (accession nos are given in parentheses). The phylogenetic tree was constructed using the ARB software package (version December 2007; Ludwig et al., 2004) and the corresponding SILVA SSURef 95 database (version July 2008; Pruesse et al., 2007). Tree building was performed with all *Streptomycetaceae* sequences available in the SILVA database using the maximum-likelihood method with fastDNAml (Olsen et al., 1994) and an *Actionbacteria* conservatory filter. All strains in the figure are type strains.

Genus I. **Streptomyces** Waksman and Henrici 1943, 339^AL emend. Witt and Stackebrandt 1990, 370 emend. Wellington, Stackebrandt, Sanders, Wolstrup and Jorgensen 1992, 159

Peter Kämpfer

Strep.to.my′ces. Gr. adj. *streptos* pliant, bent; Gr. masc. n. *mukês* fungus; N.L. masc. n. *Streptomyces* pliant or bent fungus.

Aerobic, Gram-stain-positive, non-acid-fast bacteria that form extensively branched substrate and aerial mycelia. Chemo-organotrophic, having an oxidative type of metabolism. The vegetative hyphae (0.5–2.0 µm in diameter) rarely fragment. **The aerial mycelium forms chains of three to many spores at maturity**. Some species show short chains of spores on the substrate mycelium and others form sclerotia, pycnidial-, sporangia-, and synnemata-like structures. The spores are nonmotile. **Colonies are discrete and lichenoid, leathery, or butyrous.** Often, colonies initially show a smooth surface, but later develop a weft of aerial mycelium that may appear floccose, granular, powdery, or velvety. **Can produce a wide variety of pigments responsible for the color of the vegetative and aerial mycelia. Colored diffusible pigments may also be formed.** Many strains are able to produce one or more antibiotic substances.

Catalase-positive. Generally reduce nitrates to nitrites and degrade polymeric substrates such as casein, gelatin, hypoxanthine, and starch, in addition to adenine and L-tyrosine. **Most species use a wide range of organic compounds as sole sources of carbon for energy and growth.** The temperature optimum for most species is in the range 25–35°C; some species, however, can grow at temperatures within the psychrophilic and thermophilic range; optimum pH range for growth is 6.5–8.0. The cell-wall peptidoglycan contains major amounts of **LL-A_2pm**. In some cases, low amounts of *meso*-A_2pm can be detected. **They lack mycolic acids, contain major amounts of saturated, iso- and anteiso-fatty acids, and typically possess either hexa- or octahydrogenated menaquinones with nine isoprene units as the predominant isoprenolog, although menaquinones with eight and ten isoprene units are also found. A complex polar lipid pattern is observed, containing typically diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. Widely distributed and abundant in soil, including composts.** A few species are pathogenic for animals and man, whereas some are phytopathogens.

DNA G+C content (mol%): 66–78 (T_m).

Type species: **Streptomyces albus** (Rossi Doria 1891) Waksman and Henrici 1943, 339^AL.

Further descriptive information

Morphology, fine structure, and life cycle. Early investigations of streptomycetes were dominated by a strong emphasis on morphology. The complex life cycle of streptomycetes (see below) offers three features for detailed microscopic characterization: (a) vegetative (substrate) mycelium (on solid and in liquid media); (b) aerial mycelium bearing chains of arthrospores (sometimes called "sporophores"); and (c) the arthrospores themselves (Kutzner, 1981). It is the last two categories that have provided most diagnostic information for taxonomists.

Early reports indicated that streptomycetes formed spore chains on the vegetative mycelium in both solid and liquid culture (e.g. Carvajal, 1947; Glauert and Hopwood, 1960; Tresner et al., 1967). However, it was never clarified whether these structures were analogous to the arthrospores formed on the aerial mycelium rather than deformations of the hyphae produced in staling cultures.

The fine structure and development of the aerial arthrospores have been studied extensively (Locci and Sharples, 1984). They are formed by septation and disarticulation of pre-existing hyphal elements within a thin fibrous sheath. The spore wall is formed, at least in part, from wall layers of the parent hypha; this is termed *holothallic development* (Locci and Sharples, 1984), and was found to be typical for many other sporo actinomycetes (Williams et al., 1973). The configuration of the spore chains (or sporophores) has played a very important role in species descriptions for many years. Often, the chains are long and contain more than 50 arthrospores. It is known that a number

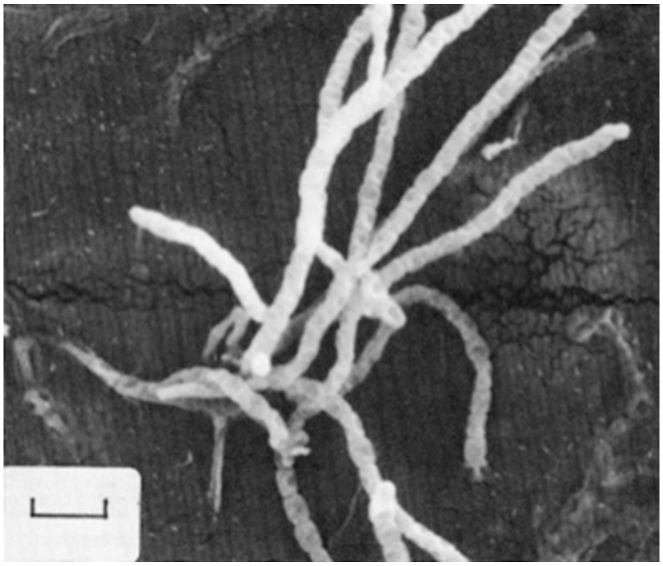

FIGURE 340. Straight to flexuous (*Rectiflexibles*) spore chains of *Streptomyces griseus*. Bar, 2 µm.

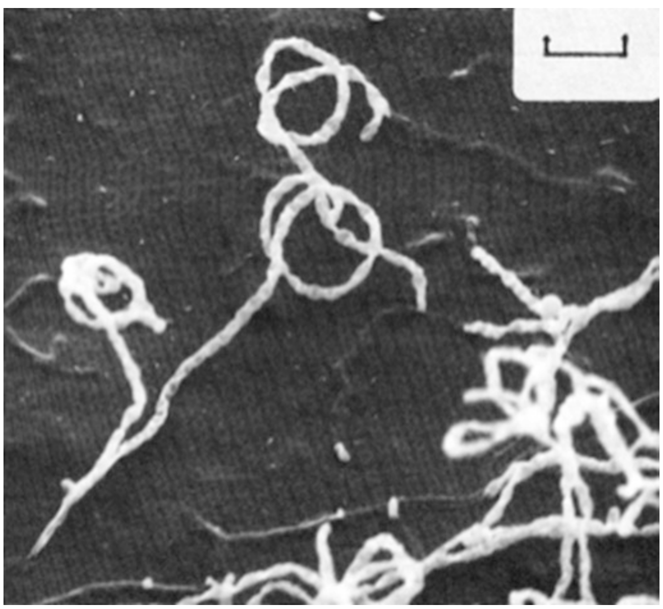

FIGURE 341. Looped (*Retinaculiaperti*) spore chains of *Streptomyces vinaceus*. Scanning electron microscopy. Bar, 5 µm.

of different genes are involved in spore formation (Chater, 1979) and that different cultivation conditions can have an influence on spore formation. The range of spore chain morphologies is extensive and some workers have recognized many categories, for example, Ettlinger et al. (1958a) grouped strains into 15 morphological types. A simpler and practical scheme was proposed by Pridham et al. (1958) and adopted for the International *Streptomyces* Project (ISP; Shirling and Gottlieb, 1966). Three categories recognized were: (a) straight to flexuous (*Rectiflexibiles*) (Figure 340); (b) hooks, loops, or spirals with one to two turns (*Retinaculiaperti*) (Figure 341); and (c) spirals (*Spirales*) (Figure 342).

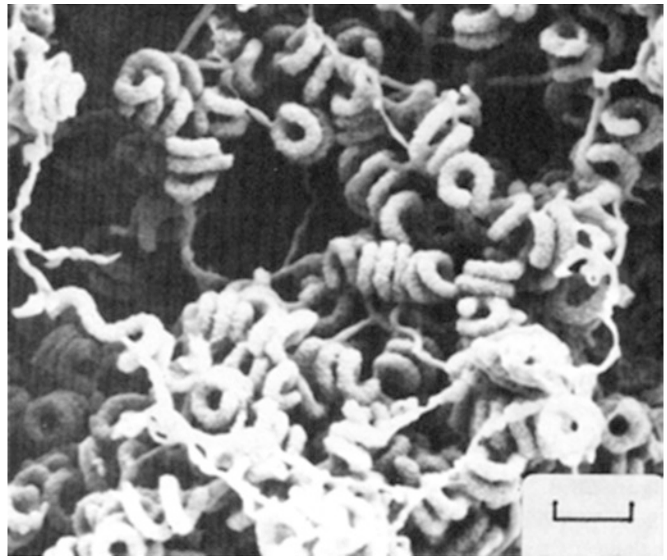

FIGURE 342. Spiral (*Spirales*) spore chains of *Streptomyces hygroscopicus*. Scanning electron microscopy. Bar, 5, µm.

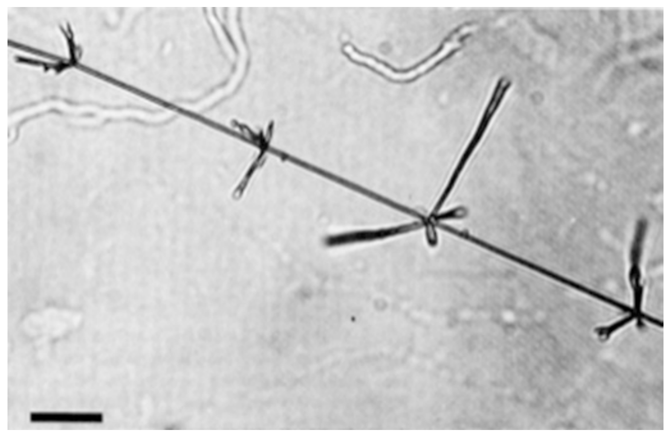

FIGURE 343. Aerial filament and initial verticils of *Streptoverticillium cinnamineum*. Light microscopy. Bar, 20 µm.

It should be noted, however, that even this simple system can pose problems, because it is not unusual that more than one category is seen in the same culture, and the distinction between *Retinaculiaperti* and *Spirales* is not always clear (Shirling and Gottlieb, 1977; Williams and Wellington, 1980). Aerial filaments can also differentiate into verticils (Figure 343, Figure 344, Figure 345, Figure 346, Figure 347, Figure 348, and Figure 349) as for most of species formerly grouped into the genus *Streptoverticillium* (Locci and Schofield, 1989).

Spore surface ornamentation has also been adopted as a taxonomic character. The ornaments, which are in fact borne on the spore sheath, can be grouped into the categories smooth, spiny, hairy, and warty. A further type, rugose, was proposed by Dietz and Mathews (1971) (Figure 350, Figure 351, Figure 352, Figure 353, and Figure 354). Spore surface ornamentation is a stable character, but the differences between smooth, warty, and rugose types can be difficult to observe. However, these problems can be resolved by using scanning electron microscopy.

Normally, streptomycetes grow by tip extension as long, branching vegetative hyphae, which rarely have septae. Often, the compartments within the substrate hyphae contain numerous copies of the chromosomal DNA (Schrempf, 2006). The formation of aerial hyphae starts in response to nutrient depletion. The aerial structures can contain several different surface layers. The hydrophobic rodlet layer, which is one of them, comprises the proteins RdlA and RdlB. The corresponding genes have been studied in *Streptomyces coelicolor* M145 and "*Streptomyces lividans*" TK23. They are expressed within growing aerial hyphae, but not within spores (Claessen et al., 2002).

Comparisons of *Streptomyces coelicolor* A3(2) and *Streptomyces griseus* have shown that these strains share several orthologous genes that are important for the development of the aerial hyphae (Chater and Horinouchi, 2003). Some of these genes, e.g. *ramC* and *ramR*, are necessary for the production of the aerial hyphae, but are not essential for vegetative growth. The production of RamC requires additional developmental regulatory genes (*bldD*, *crpA*, and *ramR*, but not *bldN* and *bldM*; O'Connor et al., 2002). The expression of different *whi* (white) genes is important for induction of curling of the aerial hyphae, their septation, and finally spore formation. In studies on *Streptomyces coelicolor* A3(2), it has been shown that some early regulatory *whi* genes (*A*, *B*, *G*, *H*, *I*, and *J*) are required for septation

during sporulation. Furthermore, the *whiA* gene plays a major role in the extension process of the development of aerial hyphae towards septation (Ainsa et al., 2000).

Studies of the full genome of *Streptomyces coelicolor* A3(2) have shown that this strain encodes about 60 sigma (σ) factors. A subfamily of nine of these σ factors is involved in the late sporulation process and σ^H is involved in the development of aerial hyphae (in addition to responses to various stresses), whereas spore maturation is governed by σ^F (Schrempf, 2006). A recently published comparative genomic analysis (Chater and Chandra, 2006) gives a more detailed insight into this complex process. The partitioning of chromosomes is observed within the aerial hyphae; a comparatively synchronous septation leads

to the compartment formation, which finally results in pore formation after maturation. Spores contain single chromosomes.

Cell division in *Streptomyces* is also a complex process. Normally, this is initiated by polymerization of the FtsZ protein on the inner surface of the cytoplasma membrane to form the Z-ring structure at the future division site (Lutkenhaus, 1997; Margolin, 2003). Studies on the transcription of genes in *Streptomyces griseus* suggest that *ftsZ* is expressed during both vegetative growth and sporulation (Dharmatilake and Kendrick, 1994). For *Streptomyces coelicolor* A3(2), it has been shown that FtsZ is required for septation within the vegetative substrate mycelium as well as for the synchronous formation of septae within the developing aerial hyphae prior to detectable partitioning of nucleoids (Grantcharova et al., 2003). The cycle of differentiation is usually observed on solid media, although for some strains [i.e. *Streptomyces griseus* (McCue et al., 1996); *Streptomyces coelicolor* A3(2) (Van Keulen et al., 2003)], sporulation in liquid culture is also reported. At the air interface of standing liquid cultures, gas vesicles may be present within the hyphae. For *Streptomyces coelicolor* A2(3), a gene cluster was reported that encoded proteins resembling gas vesicles of cyanobacteria and their homologs within halophilic archaea (Schrempf, 2006). For several *Streptomyces* strains, a transient slow down during growth in liquid culture is reported before entering the stationary phase. In this transition phase, an increase in ppGpp (guanosine 3′,5′-bispyrophosphate) and a decrease in GTP, as well as the activation of genes required for secondary metabolism, is observed. The synthesis of two ribosomal proteins is drastically reduced when the culture approaches the stationary phase (Blanco et al., 1994).

Cell-envelope composition.

Peptidoglycan. The ultrastructure and chemical composition of the cell walls of streptomycetes are typical for Gram-stain-positive bacteria (Schleifer and Kandler, 1972). Under the electron microscope, they appear as homogeneous electron-dense layers of about 16–35 nm. The cell walls are composed of peptidoglycan strands, which are multilayered. The heteropolymer peptidoglycan consists of heteropolysaccharide chains (the so-called "sugar backbone"), which are connected by peptide cross-links. The sugar backbone is composed of alternating β-1,4-linked units of the sugar derivatives *N*-acetylglucosamine and *N*-acetylmuramic acid. An oligopeptide of alternating D- and L-amino acids substitute the carboxyl group of the muramic acid (Schleifer and Kandler, 1972). In *Streptomyces*, the substitution is a tetrapeptide L-Ala–D-Glu–LL-A_2pm–D-Ala, which is cross-linked by a pentaglycine bridge extending from the C-terminal D-alanine of the peptide unit to the amino group located on the D carbon of LL-A_2pm. The resulting macromolecular structure forms the cell envelope. This LL-A_2pm–Gly_5 is also called the A3γ peptidoglycan type (Schleifer and Kandler, 1972) and is diagnostic for streptomycetes as well as some other combined-wall chemotype I actinomycetes (Lechevalier and Lechevalier, 1970a, 1970b, 1970c).

Lechevalier and coworkers used specific amino acids in purified cell walls to group aerobic actinomycetes into four so-called "wall chemotypes". Cell walls with *meso*-A_2pm and LL-A_2pm were the first to be detected. Cell-wall composition can vary with the developmental stage of streptomycetes. Takahashi et al. (1984) reported that submerged mycelium of strains having a cell wall with *meso*-A_2pm and LL-A_2pm consists of LL-A_2pm and glycine (wall chemotype I), whereas in the spores only *meso*-A_2pm could be detected (wall chemotype III according to Lechevalier and Lechevalier, 1970a, 1970b, 1970c). The quantitative distribution of cell-wall amino acids and cell-wall sugars differed in the cell-wall composition of aerial, substrate, and submerged mycelia of 11 streptomycetes. *N*-Acetylmuramic acid is found in the glycolyl type in the cell walls of *Streptomyces*, as in all other actinomycetes (Uchida and Aida, 1977).

Muramic acid phosphate residues are essential as attachment points to teichoic acids; the latter are polymeric substances containing repeating phosphodiester groups. They consist of polyols (i.e. the sugar alcohols glycerol and ribitol) or *N*-acetylamino sugars or both and are valuable for the identification of Gram-stain-positive bacteria. The structure of teichoic acids does not differ between streptomycetes and other Gram-stain-positive bacteria. The polymers consist either of ribitol phosphate or glycerol phosphate. Significant for the teichoic acids of actinomycetes is the absence of ester-bound D-alanine; instead, ester-linked acetic acid and sometimes succinic acid residues are present (Naumova et al., 1980).

The synthesis of either ribitol phosphate (e.g. *Streptomyces streptomycinii* and *Streptomyces violaceus*) or glycerol phosphate polymers (e.g. *Streptomyces antibioticus, Streptomyces levoris, Streptomyces rimosus*, and *Streptomyces thermovulgaris*) has been reported in streptomycetes (Naumova et al., 1980). In ribitol teichoic acids, positions 1 and 5 of ribitol are connected to the phosphates, but in glycerol teichoic acids, position 1 is commonly connected to 3, and, in other types, links to 2 (as in *Streptomyces antibioticus*) are uncommon. Polyol phosphates can be substituted with various combinations of sugars or amino sugars or both. The sugars or amino sugars are linked to glycerol or ribitol via glycosidic bonds. The role of teichoic acid in the taxonomy of *Streptomyces* is not clear as only a few strains have been analyzed in detail (Naumova et al., 1980).

Cell-wall polysaccharides. Cell-wall polysaccharides seem to be of no diagnostic value (Lechevalier et al., 1971) for strains that have LL-A_2pm in their cell wall. Occasionally, diagnostic sugars found in actinomycetes (e.g. arabinose, galactose, and xylose) have been reported in streptomycetes. The presence of diagnostic sugars in streptomycetes was extensively sought by Kroppenstedt (1977) who analyzed hundreds of strains. Glucose, mannose, and ribose are usually found in small amounts.

Phospho- and glycolipids. The lipids of streptomycetes consist mainly of diphosphatidylglycerol, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylinositol mannosides. A summary of the lipid composition of actinomycetes can be found in Lechevalier et al. (1977). Glycolipids cannot be used for the identification of streptomycetes because they do not occur consistently and culture conditions largely determine their qualitative and quantitative lipid composition. Glycolipid content increases significantly under phosphate-limiting conditions.

Polar lipids have a significant taxonomic value in actinomycetes, as demonstrated by Lechevalier et al. (1977). The phospholipids of 97 actinomycete strains, representing 20 genera, were analyzed and assigned to five phospholipid types by Lechevalier et al. (1977). The phospholipid groups are characterized by the absence or presence of certain nitrogenous phospholipids. Members of the family *Streptomycetaceae* have phospholipid type II. The marker lipids of this type are phosphatidylethanolamine, methyl-phosphatidylethanolamine, hydroxy-phosphatidylethanolamine, and lyso-phosphatidylethanolamine, although differentiation can be made using additional lipids (e.g. phosphomonoester and hydroxy-phosphatidylethanolamine) and the presence or absence of phophatidylglycerol and phosphatidylinositol.

Menaquinones. Streptomycetes contain only menaquinones (Collins and Jones, 1981). The synthesized quinones have a partly saturated isoprenoid side chain at position 3 of the naphthoquinone ring. In this, streptomycetes resemble the majority of actinomycetes. Menaquinone composition has a great taxonomic value for the differentiation of actinomycetes. The following three variations are useful for classification and identification: 1) the different numbers of isoprene units; 2) the different degree of hydrogenation; 3) and the position of hydrogenated isoprene units (Figure 355, Table 264). The

[j]For details see Stackebrandt and Schumann (2006).

menaquinones of streptomycetes have a highly hydrogenated isoprenoid chain and three to four (rarely five) saturated isoprene units. The actinomycetes, which belong to this type, can be differentiated by a different degree of saturation.

Fatty acids. *Streptomyces* species synthesize terminally branched fatty acids. 2-Methylbutyrate as a starting compound results in anteiso-branched fatty acids with an odd number of carbon atoms. In contrast, isovalerate and isobutyrate as starting compounds lead to the formation of iso-branched fatty acids with even and odd numbers of carbon atoms, respectively. For this reason, iso- and anteiso-branched fatty acids appear in pairs with odd numbers of carbon atoms only (Figure 356).

Colonial characteristics. Streptomycetes have many differential colonial features, such as pigmentation of spores, substrate mycelium, and diffusible exopigments, together with the morphology of colonies and the texture of the aerial mycelium. The production of different pigments has been widely used in classification and identification, but it is important to mention that colony morphology is too variable for use as a taxonomic character.

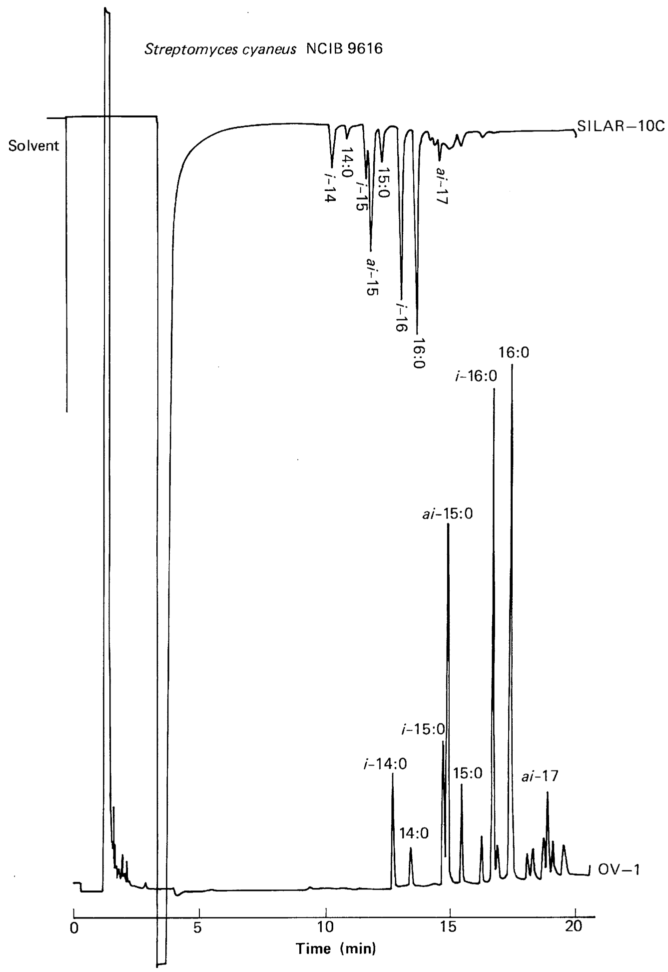

FIGURE 356. Gas chromatographic analysis of the fatty acid methyl esters of *Strepotomyces cyaneus* NCIB 9616.

One feature, widely used in streptomycete taxonomy, is spore mass color. Strains showing different spore colors have been assigned to "sections", "series", and "species-groups" (Burkholder et al., 1954; Ettlinger et al., 1958a; Flaig and Kutzner, 1954, 1960b; Gauze et al., 1957; Hesseltine et al., 1954; Krasil'nikov, 1960; Pridham et al., 1958). In the 8th edition of *Bergey's Manual* (Pridham and Tresner, 1974a), *Streptomyces* species were assigned to seven color series: Blue, Gray, Green, Red, Violet, White, and Yellow. In a later survey, the series were extended to accommodate additional colors (Kutzner, 1981). The color of the spore mass is still useful, but its determination may be difficult, because the color can be influenced by factors such as the medium, growth regime, and age of the culture. Sometimes, the color cannot clearly be attributed to any established category.

The color of the substrate mycelium and the soluble pigment are of high value when they are striking, e.g. blue, dark green, red, and violet. The color of the substrate mycelium has been used in a preliminary approach to group streptomycetes (Baldacci, 1958; Baldacci et al., 1954; Krasil'nikov et al., 1961), but again, the expression of the various pigments is often influenced by the medium composition, temperature, pH, and age of culture (Kutzner, 1981). Also, diffusible pigments and their pH sensitivity have been used as taxonomic characters (Jensen, 1930; Shirling and Gottlieb, 1970; Waksman and Curtis, 1916), but it may be that chemically different pigments exhibit the same color (Krasil'nikov, 1970a; Kutzner, 1981). Some *Streptomyces* strains produce anthracyclinglycoside, diazaindophenol, naphthoquinone, phenoxazinone, and prodigiosin pigments (Kutzner, 1981).

Despite the problems, determinations of aerial spore mass color, substrate mycelium color, and diffusible pigments were used for the descriptions of *Streptomyces* species in the ISP (Shirling and Gottlieb, 1966). It was important that the color determinations were based on standardized media and methods, but there was some disagreement on aerial spore color determination using the Tresner and Backus (1963) color chart. The diagnostic value of spore color was limited because over half of the test strains were placed in the Gray series. Good agreement was found for the determinations of pH sensitivity of the diffusible pigments, but not in the interpretation of substrate mycelium color (Shirling and Gottlieb, 1970).

Genetics and genomics. The genetics of streptomycetes is a rapidly developing topic and a wealth of information has been published within the last few years (for reviews and more information see, for example: Chen et al., 2002; Donadio et al., 2002; Paradkar et al., 2003; Schrempf, 2006; Ventura et al., 2007; Hopwood, 2003, 2007; Hsiao and Kirby, 2008; Dyson, 2010; and references therein). It is, of course, far beyond the scope of this short chapter to give a comprehensive summary of all the recent findings in this exciting area of research; however, despite this, it is not clear at present how this information can be used for taxonomic purposes.

The literature on *Streptomyces* genomes is extensive and information on the complex structure of genomes is increasing, mainly because streptomycetes are very abundant and important as soil inhabitants, where they are regarded as major agents in the cycling of organic carbon compounds. They are also able to produce many and diverse hydrolytic exoenzymes, like chitinases and cellulases. Summaries on their genomics and genetics are available (Paradkar et al., 2003; Schrempf, 2006; Ventura et al., 2007) and, hence, this paragraph is intended to give only a very short summary of existing knowledge on *Streptomyces* genetics.

In particular, one strain, *Streptomyces coelicolor* A3(2), is of major importance as it represents a major model organism for studying developmental complexity. In addition, streptomycetes are the most important natural source of antibiotic compounds and other bioactive metabolites. The whole genome sequences of strains of *Streptomyces* species have been studied and are published or available online: *Streptomyces coelicolor* A3(2) (representing the model streptomycete), *Streptomyces ambofaciens* strains ATCC 15154, DSM 40697, ETH 9247, and ETH 11317 (*Streptomyces ambofaciens* is known for its remarkable genetic instability), *Streptomyces avermitilis* MA-4680^T (the producer of avermectin), *Streptomyces griseus* subsp. *griseus* NBRC 13350 (producer of bioactive secondary metabolites), and *Streptomyces scabiei* 87.22 (causing potato scab).

All *Streptomyces* strains studied so far contain a large genome, which can be circular or linear. The linearity cannot be simply deduced from the extensive genetic linkage mapping of *Streptomyces coelicolor* and is not regarded to be linked with mycelial growth.

The *Streptomyces coelicolor* A3(2) genome was considered to be circular, but on the basis of studies on cosmid libraries in combination with comparisons of physical maps from the wild-type and mutant strains of *Streptomyces coelicolor* A3(2) and "*Streptomyces lividans*", it is quite likely that the chromosome occurs in circular and linear forms (Lin et al., 1993; Redenbach et al., 1996). Pulse-field gel electrophoresis (PFGE) studies have revealed the presence of a linear chromosome in other streptomycetes, including *Streptomyces ambofaciens* (Leblond et al., 1996), *Streptomyces antibioticus*, *Streptomyces moderatus*, *Streptomyces lipmanii*, *Streptomyces parvulus*, *Streptomyces rochei* (Lin et al., 1993), *Streptomyces griseus* (Lezhava et al., 1995), and *Streptomyces hygroscopicus* (Pang et al., 2002a, 2002b). A linear arrangement of the chromosome has also been shown for a *Streptoverticillium* sp. (Redenbach et al., 1998).

The *Streptomyces coelicolor* A3(2) chromosome contains about 8667 Mbp, which corresponds to 7825 genes. Twenty gene clusters encode known or predicted secondary metabolites (Bentley et al., 2002). It is noteworthy that the *Streptomyces coelicolor* chromosome was shown to carry more genes (i.e. 7825) than the eukaryote *Saccharomyces cerevisiae* (containing 6203 genes). The *Streptomyces avermitilis* MA-4680^T genome was shown to comprise about 9025 Mbp (mean G+C content 70.7 mol%), which corresponds to 7574 potential open reading frames, 35% of which constitute 721 paralogous families (Ōmura et al., 2001; Ventura et al., 2007). Thirty gene clusters encode secondary metabolites. It was found that one region of 6500 Mbp has been highly conserved with respect to gene order in the *Streptomyces avermitilis* MA-4680^T and *Streptomyces coelicolor* A3(2) genomes and, hence, may contain essential genes. The terminal regions are not conserved and contain "nonessential genes" (Ikeda et al., 2003). It is interesting to note that an ancient synteny (conservation of gene order) has been revealed between the central core of the *Streptomyces coelicolor* A3(2) chromosome and the whole chromosomes of *Corynebacterium diphtheriae* and *Mycobacterium tuberculosis* (Bentley et al., 2002).

Whole-genome synteny plots have shown a high conservation of the overall position and orientation of common genes in the chromosomes of *Streptomyces coelicolor* A3(2) and *Streptomyces avermitilis* MA-4680^T (Ventura et al., 2007). Ikeda et al. (2003) showed that about two-thirds (5283) of the genes of these strains represent conserved orthologs (estimated by reciprocal BLAST analysis). Similarly, 4837 genes were found to be orthologous between these two strains (Ventura et al., 2007). When *Streptomyces scabiei* ATCC 49173^T is added to this comparison, the number of genes conserved among the three strains drops to 4190 and, as pointed out by Ventura et al. (2007), a four-way analysis, including the hitherto unpublished sequence of *Streptomyces venezuelae* ATCC 10595, reduces the number to 3566. It can be expected that the number will fall further as more *Streptomyces* genomes become available. Ventura et al. (2007) pointed out that only about 17% of the 3566 genes common to the four *Streptomyces* genomes are present in *Escherichia coli* K-12 and *Bacillus subtilis* 168.

Hsiao and Kirby (2008) used DNA–DNA microarray hybridization to compare the genome content of *Streptomyces avermitilis* ATCC 31267^T, "*Streptomyces cattleya*" ATCC 35852, "*Streptomyces maritimus*" Yang-Ming and *Kitasatospora* (*Streptomyces*) *aureofaciens* ATCC 10762^T with that of *Streptomyces coelicolor* A3(2). About 93% agreement with the genome sequence data available for *Streptomyces avermitilis* ATCC 31267^T was shown and a number of trends in the genome structure for *Streptomyces* and closely related *Kitasatospora* species could be detected. The core central region was well conserved and a low degree of gene conservation in the terminal regions of the linear chromosome was observed across all four strains. Between these regions, two areas of intermediate gene conservation were detected by microarray analysis though some conserved genes were also identified within the terminal regions.

The replication process of the *Streptomyces* chromosome has been summarized by Schrempf (2006) and Ventura et al. (2007). The replication of linear *Streptomyces* chromosomes and plasmids is initiated from a fairly centrally located replication origin rich in DnaA box sequences and proceeds bidirectionally towards the telomeres. The chromosomal replication origin (*oriC*) region was found to be highly conserved in *Streptomyces coelicolor* A3(2) (Calcutt and Schmidt, 1992), "*Streptomyces lividans*" 66 (Zakrzewska-Czerwinska and Schrempf, 1992), "*Streptomyces lividus*" TK21, *Streptomyces antibioticus* ETH 7451,

and *Streptomyces chrysomallus* ATCC 11523^T (Jakimowicz et al., 1998). Interestingly, it was found that contrary to the high overall G+C content (69–73 mol%) of *Streptomyces* DNA, the region of the origin (*oriC*) is rich in A+T (64 mol%). The chromosomal ends of some *Streptomyces* species have been shown to contain terminal inverted repeats (TIRs), which are covalently bound to proteins, most likely at their 5′ ends. TIR lengths among available sequenced *Streptomyces* chromosomes vary considerably: 174 bp for *Streptomyces avermitilis*; 18,488 bp for *Streptomyces scabiei*; 21,653 bp for *Streptomyces coelicolor* M145; and approximately 198 kb for *Streptomyces ambofaciens* (Ventura et al., 2007).

The telomeres are replicated by a special mechanism which is initiated by priming from a terminal protein covalently bound to the 5′ ends. Approximately 250–320 nucleotides at these ends are characteristic and possess a complex secondary structure (Ventura et al., 2007).

The origin of the linearity of the *Streptomyces* chromosome is thought to have occurred by single-crossover recombination between an initially circular chromosome and a linear plasmid. Several examples of exchange of ends between chromosomes and linear plasmids, resulting in hybrid molecules with different right and left ends, have been reported.

The genomes of streptomycetes contain several examples of apparent redundancy of metabolic genes, which is thought to be due to the complex morphological and physiological differentiation of streptomycetes. The metabolic genes comprise genes that encode functions involved in carbon storage transactions, genes specific for different hyphal cell types, genes comprising enzymes of the pentose phosphate pathway, and multiple *fabH*-like genes, which are important for the first step in fatty acid biosynthesis (some of these are linked with secondary metabolism gene sets) (Ventura et al., 2007). Interestingly, some genes are not present in streptomycetes. Two of the three subunits of exonuclease V (the *recB* and *recC* genes), for instance, are not found in streptomycetes, though they are present in other actinobacteria such as mycobacteria. The XerCD pathway, which is responsible for the resolution of circular chromosomes after replication, is absent from streptomycetes, a result in line with the linearity of *Streptomyces* chromosomes. The conserved *ftsA* gene, which is widely distributed in the domain *Bacteria* and involved in the complex cell division process, is generally absent from actinobacteria. In addition, the *minC* and *minE* genes, which are involved in the choice of division site in many unicellular bacteria are not found in *Streptomyces* strains (Ventura et al., 2007).

Streptomyces colonies often show a high spontaneous variability in antibiotic biosynthesis, pigmentation, and sporulation. The various antibiotic resistances, A-factor formation, and synthesis of tyrosinase or arginosuccinate are encoded by unstable genes. It is possible to stimulate this genetic instability by mutagens, such as ethidium bromide, mitomycin, ultraviolet light, and by gyrase- (topoisomerase II) inhibiting antibiotics. Often, these variations can be attributed to large chromosomal deletions, preferentially occurring at the telomeric and subtelomeric regions, and including up to 2 Mbp of DNA (Chen, 1995; Hütter and Eckhardt, 1988; Leblond and Decaris, 1994; Schrempf et al., 1989). More details about these processes are given by Schrempf (2006). The variability of the chromosomal DNA is further increased by its interaction with linear and circular plasmids, phages, transposons, and insertion elements. Streptomycetes inhabit quickly changing environments and, hence, the high plasticity of the genome is likely an effective prerequisite for quick adaptation.

Streptomyces extrachromosomal elements. Many plasmids have been described (for a review, see Kieser et al., 2000). Linear plasmids, often very large, are widespread and diverse among streptomycetes, but circular plasmids are also found. The various types of circular plasmids differ in size. Schrempf et al. (1989) isolated the low-copy number circular plasmid SCP2 from a streptomycete and this is used as a cloning vector. The plasmid SCP2* (a variant of SCP2; Hopwood et al., 1985) has been sequenced and encodes 34 proteins, most of them of unknown function. The replication region was shown to contain the *repI* and the *repH* genes, both encoding small proteins. The *traA* gene, essential for DNA transfer and pock-formation, was identified in addition to 10 additional genes, which are thought to be involved in conjugation and DNA spreading. Plasmid pIJ101 (about 8.8 kb) is a high-copy-number natural conjugative *Streptomyces* plasmid. On this plasmid, regions for its replication, stability, transfer and distribution have been identified. Efficient conjugation among streptomycetes necessitates the plasmid-encoded *tra* gene and the *cis*-acting locus of transfer (Ducote et al., 2000). A further natural plasmid, pSG5 (initially found in *Streptomyces ghanaensis* DSM 2932), of about 12.3 kb, is naturally temperature-sensitive and cells may contain approximately 50 copies per chromosome. Additional multicopy plasmids pSN22 (Kataoka et al., 1991), pJV1 (Bailey et al., 1986), and pSMA2 (Pernodet et al., 1984) replicate via a rolling circle mechanism (Hagege et al., 1993; Servín-González, 1993).

Linear plasmids are also common in streptomycetes; however, knowledge of their encoding functions is still restricted to few functions. These include antibiotic production (Gravius et al., 1994; Kinashi et al., 1991) and mercury resistance (Ravel et al., 1998). Some of the linear plasmids are efficiently transferred during conjugation. The replication mechanism is best understood for pSLA2, initiated bidirectionally near the center and proceeding towards its telomeric ends, generating 3′ leading-strand overhangs. It should be mentioned that several other members of the order *Actinomycetales* harbor genes on linear plasmids, among them those required for isopropylbenzene and trichlorethylene catabolism (*Rhodococcus erythropolis*; Kebeler et al., 1996), biphenyl degradation (*Rhodococcus erythropolis* and *Rhodococcus globerulus*; Kosono et al., 1997), hydrogen autotrophy (*Rhodococcus opacus*, formerly "*Nocardia opaca*"; Kalkus et al., 1993), and fasciation in plants (*Rhodococcus fascians*; Crespi et al., 1992). Linear plasmids have also been discovered for mycobacteria (*Mycobacterium avium*, *Mycobacterium branderi*, *Mycobacterium celaturum*, and *Mycobacterium xenopi*). Their termini are similar to those of linear plasmids from *Streptomyces* and *Rhodococcus* species (Picardeau and Vincent, 1998); it is an open question whether circular and linear plasmids are exchanged during conjugation amongst actinomycetes. Relatively little is known about *Streptomyces* transposons; a summary of this topic is available (Schrempf, 2006). Phages with broad or narrow host ranges can be obtained from soil and several of them have been used for classifying strains (for review, see Kutzner, 1981). However, in current taxonomic studies, phage host range studies are not carried out.

DNA regions in mycelial actinobacterial genomes acquired by HGT. Despite the gross synteny between the central regions

of *Streptomyces* genomes, there are hundreds of insertion-deletion (indel) differences between *Streptomyces coelicolor* A3(2) and *Streptomyces avermitilis* MA-4680^T, most of them involving one or a few genes. This often makes it difficult to recognize synteny at the level of small groups of genes. Streptomycetes also have numerous larger islands of species-specific DNA (Ventura et al., 2007). Prior to the publication of other *Streptomyces* genome sequences, 14 islands of likely laterally acquired DNA were found by Bentley et al. (2002) in the *Streptomyces coelicolor* A3(2) genome on the basis of gene content, atypical G+C content, and location next to a tRNA determinant. Around 50% of these islands were shared with *Streptomyces ambofaciens*. From this, it is clear that in pairwise synteny plots the genes in the "subtelomeric arms" of *Streptomyces* chromosomes are much less conserved between species than those in the central regions or "cores" and that the cores contain most of the genes conserved with other actinobacteria (Bentley et al., 2002; Choulet et al., 2006; Ikeda et al., 2003).

Production of extracellular enzymes. Streptomycetes are widely distributed in soil and play an important role in the recycling of organic matter. It is not surprising, therefore, that *Streptomyces* genomes encode high numbers of predicted secreted proteins; the approximately 800 proteins in *Streptomyces coelicolor* A3(2) have been found to comprise 147 hydrolases, of which seven are cellulases and five are chitinases (Bentley et al., 2002; Ventura et al., 2007). Almost all *Streptomyces* strains studied so far can use chitin not only as a carbon, but also as a nitrogen source (Blaak and Schrempf, 1995) and, often, several chitinases are produced (Miyashita et al., 1991; Robbins et al., 1988). For more details, see Schrempf (2006). Amylases and their inhibitors are also common in streptomycetes. An α-amylase gene (*aml*) of *Streptomyces limosus* ATCC 19778^T has been cloned by Virolle and Bibb (1988). It can be deduced from sequence information that the *Streptomyces coelicolor* A3(2) genome has many genes which code for glucosyltransferases. In addition, xylanases and their genes have been identified from several streptomycetes, i.e. "*Streptomyces lividans*" 10-164 (Pagé et al., 1996), *Streptomyces halstedii* JM8 (Ruiz-Arribas et al., 1998), and the thermophilic *Streptomyces thermoviolaceus* OPC-520 (Tsujibo et al., 1997). Laccases, including those produced by *Streptomyces cyaneus* CECT 3335, can be efficiently applied for biobleaching of kraft pulps (Arias et al., 2003).

Extracellular proteases are widely distributed among streptomycetes and several corresponding genes have been characterized (Kim and Lee, 1995). Streptomycetes also contain many genes for protease inhibitors (Taguchi et al., 1996), including leupeptin and subtilisin (Hiraga et al., 2000). In addition, keratinases are frequently found (for review, see Kutzner, 1981). A few extracellular lipases and their genes have been studied from different *Streptomyces* strains (Servín-González et al., 1997; Sommer et al., 1997), among them lipolytic enzymes expressed by *Streptomyces rimosus* R6-554W (Vujaklija et al., 2002).

Jendrossek et al. (1997) found out that *Streptomyces* strains are the predominant community members of latex rubber-degrading actinomycetes. Some streptomycetes can produce enzymes involved in the modification of pharmacologically relevant compounds and xenobiotics (Peczynska-Czoch and Mordarski, 1988).

Primary metabolism. In contrast to secondary metabolism, relatively few studies have been published on the primary metabolism of streptomycetes. Some genes, among them those encoding key enzymes, like fructose-1,6-bisphosphate aldolase and glucose-6-phosphate dehydrogenases, have been identified. Butler et al. (2002) identified two *zwf* genes determining isozymes of glucose-6-phosphate dehydrogenases [the first enzyme in the oxidative pentose phosphate pathway (PPP)] and one gene (*devB*) encoding 6-phosphogluconolactonase in "*Streptomyces lividans*" 66. The PPP and the tricarboxylic acid cycle relative to glucose uptake have been studied in *Streptomyces noursei* ATCC 11455^T (Jonsbu et al., 2001).

Similar to enteric bacteria, glutamine synthetase I (GSI) in *Streptomyces coelicolor* A3(2) is post-translationally controlled by adenylyltransferase (Hesketh et al., 2002a). A novel class of glutamate dehydrogenases (GDHs) has been detected in *Streptomyces clavuligerus* NRRL 3585^T (Minambres et al., 2000). In addition, *Streptomyces coelicolor* A3(2) can utilize fatty acids (C4 to C18) as sole carbon sources (Banchio and Gramajo, 1997) and the glyoxylate cycle also seems to be present, at least in *Streptomyces clavuligerus* NRRL 3585^T (Soh et al., 2001). Malonate is a well-known competitive inhibitor of succinate dehydrogenase. Kim and Goodfellow (2002) used the genes *matB* and *matC* in generating strain variants of *Streptomyces* used for the production of antibiotics.

The pathways and genes required for the biosynthesis of primary compounds, including their regulation pattern (Rodríguez-García et al., 1997), should be studied in more detail, in order to improve knowledge on metabolic fluxes (Obanye et al., 1996). This will certainly improve the biotechnological production of pharmacologically active compounds derived from primary metabolites. Detailed analyses of proteins involved in primary and secondary metabolism are available (Hesketh et al., 2002b; Huang et al., 2001). Proteomic and metabolomic data are currently being studied (e.g. Novotna et al., 2003).

Secondary metabolism. Streptomycetes have been the most important source of antibiotics since the discovery of actinomycin D, streptothricin, and streptomycin in the 1940s by Waksman and coworkers (for a review, see Hopwood, 2007). Streptomycetes synthesize a large variety of chemically different compounds, many of them acting as antibiotics, cytostatics, fungicides, or as modulators of immune responses (see e.g. Horinouchi, 2002; Bérdy, 2005; Challis and Hopwood, 2003; Van Wezel and Vijgenboom, 2004; and Hopwood, (2007) for more detailed information). Consequently, the study of *Streptomyces* genomes has been of great interest and has led to the discovery of 23 gene sets that code for these compounds in the *Streptomyces coelicolor* A3(2) chromosome and 30 in that of *Streptomyces avermitilis* MA-4680^T (Ventura et al., 2007). It is interesting that many of these gene sets are present in one genome, but not in others, and that the same position in different chromosomes can be occupied by different secondary metabolism clusters. For example, the *pks1* cluster of *Streptomyces avermitilis* MA-4680^T is replaced in *Streptomyces ambofaciens* ATCC 23877^T by a different secondary metabolism cluster of 28 genes and in *Streptomyces coelicolor* A3(2) by a 31-gene insertion (Choulet et al., 2006).

The subtelomeric chromosome arms often contain gene clusters for secondary metabolism, especially those that are

species-specific. The more abundant genes for secondary metabolism, such as those for the production of pentalenolactone, different siderophores, and the odor compound geosmin, typically fall in syntenous locations within the central core region (Bentley et al., 2002; Ikeda et al., 2003). It is known that certain linear plasmids may also carry such clusters, thereby explaining the impact of lateral gene transfer between chromosomes present in different streptomycetes (Ventura et al., 2007).

The genes encoding different pharmacologically active substances of importance are located within DNA stretches of 20 kb to more than 100 kb. Successful cloning has been achieved by complementing mutants, by screening total genomic DNA or gene libraries with homologous or heterologous gene probes generated by cloning, or with the help of PCR, as well as by transposon mutagenesis (Schrempf, 2006). It is interesting that the genes for the biosynthesis of antibiotics are frequently located near one or more genes mediating resistance to the corresponding antibiotic. The following listing has been adapted from Schrempf (2006). The gene-cluster for the synthesis of the polyketide actinorhodin was achieved by complementation of mutants (Malpartida and Hopwood, 1984). Other gene clusters for polyketides were cloned using a gene-probe for the predicted key step for polyketide synthesis. These polyketides include: daunorubicin (Stutzman-Engwall and Hutchinson, 1989), frenolicin (Bibb et al., 1994), granaticin (Sherman et al., 1989), griseusin B (Yu et al., 1994), jadomycin B (Han et al., 1994), mithramycin (Lombo et al., 1996), tetracyclines (Binnie et al., 1989), tetracenomycin C (Motamedi and Hutchinson, 1987), tetrangomycin (Hong et al., 1997), and urdamycin A (Decker and Haag, 1995).

Genes for several clusters of macrolides have been identified, including the genes for carbomycin (Epp et al., 1987), tylosin (Fishman et al., 1987), oleandomycin (Swan et al., 1994), and rapamycin (Schwecke et al., 1995). Genes for peptide antibiotics [such as actinomycin (Hsieh and Jones, 1995; Stindl and Keller, 1994) and biolaphos (Murakami et al., 1986)], and cyclopentenoid antibiotics (such as methylenomycin; Chater and Bruton, 1985) have also been found. Additionally, genes have been detected for the synthesis of nikkomycin (a nucleoside-peptide; Bormann et al., 1996), nosiheptide (a thiopeptide; Dosch et al., 1988), undecylprodigiosin (a pyrrole; Feitelson and Hopwood, 1983; Malpartida et al., 1990), ansamycins [such as rubradirin (Sohng et al., 1997) and rifamycin (August et al., 1998)], aminoglycosides [such as puromycin (Lacalle et al., 1992) and streptomycin (Distler et al., 1987; Ohnuki et al., 1985)], carbapenems (Nakata et al., 1989), cephamycin (Aharonowitz et al., 1992; Paradkar et al., 1996), and cyclopilins (Pahl et al., 1997). Again, it is far beyond the scope of this chapter to give a comprehensive overview on the secondary metabolism of streptomycetes, which are covered in text books and/or reviews (e.g. Bérdy, 2005; Challis and Hopwood, 2003; Van Wezel and Vijgenboom, 2004; Hopwood, 2007; Dyson, 2010).

Ecology. Streptomycetes can be isolated in high numbers from soil, which is their primary natural habitat. As mentioned above, most streptomycetes can degrade complex and recalcitrant plant and animal materials, often polymeric residues including polysaccharides (e.g. cellulose, chitin, pectin, and starch), proteins (e.g. elastin and keratin), aromatic compounds, and lignocellulose. The biodegradative activities of actinomycetes have been the subject of several reviews (Crawford, 1988; Lechevalier, 1988; Peczynska-Czoch and Mordarski, 1988). Streptomycetes are able to degrade lignin, which occurs in nature together with cellulose and xylan (hemicellulose) in a lignocellulose complex. Experiments with ^{14}C-labeled lignin showed that streptomycetes (Antai and Crawford, 1981; Crawford, 1978), as well as other genera of actinomycetes, are involved in lignin decomposition (McCarthy et al., 1984, 1986; McCarthy and Broda, 1984), although fungi play a more important role in this process (Crawford, 1981; Janshekar and Fiechter, 1983; Kirk and Farrell, 1987). Ligniolytic streptomycetes can degrade the cellulose of the lignocellulose complex. For more details, see Ramachandra et al. (1988), Wang et al. (1990), Crawford et al. (1993), Chamberlain and Crawford (2000), Kormanec et al. (2001), Gottschalk et al. (2003), and Kaneko et al. (2003).

In addition, mesophilic and thermophilic streptomycetes have been reported to contain multicomponent cellulases, which consist of several endoglucanases and exoglucanases (Crawford and McCoy, 1972; Enger and Sleeper, 1965; Harchand and Singh, 1997; MacKenzie et al., 1984; Marri et al., 1997; Ulrich and Wirth, 1999; Wirth and Ulrich, 2002). Xylanases, which are involved in the decomposition of the lignocellulose complex, seem to be widespread among thermophilic actinomycetes, although they have also been found in mesophilic streptomycetes (Deobald and Crawford, 1987; Godden et al., 1989; Kluepfel and Ishaque, 1982; Kluepfel et al., 1986; McCarthy et al., 1985; Morosoli et al., 1999; Schäfer et al., 1996). Other polymeric compounds found in streptomycetes include pectinolytic complexes (Sato and Kaji, 1975, 1977, 1980a, 1980b) and chitinolytic complexes, which consist of chitinase and chitobiase, and have generally been isolated in full from *Streptomyces griseus* (Berger and Reynolds, 1958), *Streptomyces antibioticus* (Jeuniaux, 1966), and other streptomycetes (Beyer and Diekmann, 1985). More details are given by Schrempf (2006).

Starch, which is the primary material for the textile, paper, and food industries, can be degraded by a wide variety of fungi and bacteria. The enzymes involved are amylases, some of which have been found in several streptomycetes (Fairbairn et al., 1986; McKillop et al., 1986; Mordarski et al., 1970; Suganuma et al., 1980).

Next to degrading polymeric compounds, streptomycetes have the ability to degrade other organic materials, e.g. cotton and plant fibers (Khan et al., 1978; Lacey and Lacey, 1987), wool (Noval and Nickerson, 1959), hydrocarbons in jet fuel and emulsions (Genner and Hill, 1981), rubber (Cundell and Mulcock, 1975; Hutchinson et al., 1975), and plastics (Pommer and Lorenz, 1986). Lacey (1988) and Behal (2000) give a detailed review about the biodegradation of natural and synthetic substances. More details are given by Schrempf (2006).

In soil, streptomycetes can show pronounced mycelial growth. In this habitat, they are adapted to various, often quickly changing physical conditions (e.g. shifts in aeration, drought, frost, hydrostatic pressure and anaerobic conditions, moisture tension, and pH) by the formation of spores, which are semidormant stages in the life cycle and can survive in soil for long periods (Ensign, 1978; Mayfield et al., 1972). Viable cultures of cells have been reported by Morita (1985) from 70-year-old soil samples. Streptomycetes are almost always present as inactive spores in soil. One disadvantage of persisting as a spore is

the very low germination efficiency, which may be caused by competition with other micro-organisms. Spores which pre-germinate can grow for a short time and then resporulate (Lloyd, 1969). Several factors may be responsible for the germination of spores. Next to special signaling factors, the presence of exogenous nutrients, water, and Ca^{2+} seems to be necessary (Ensign, 1978). In addition to germination, nutrients influence the extent of hyphal growth and the time of differentiation into aerial hyphae. Fodders and other organic material, freshwater, and marine habitats, as well as potable water systems, can come into contact with soil (Korn-Wendisch and Kutzner, 1992), e.g. through human and other activities. Natural substrates (e.g. grain, hay, fodder, and wood) and synthetic products (e.g. cotton textiles, fabric, paper, rubber, plastics, and plasticizers), which can be found in or transported to soil, can be degraded with the help of mesophilic and especially thermophilic streptomycetes. The contamination of creeks and rivers with soil streptomycetes is due to drainage, e.g. after heavy rainfalls. Streptomycetes find their way into the sediments of the lakes, rivers, and, after transport to the sea, into marine sediments. It may be possible that drinking water supplies become contaminated with streptomycetes. This is a problem because the compounds produced by some streptomycetes are odorous and lead to the spoilage of the water.

Streptomycetes as plant pathogens. Some of the many saprophytic *Streptomyces* species are plant pathogens which may cause economically important diseases, including potato scab. *Streptomyces scabiei* can still be regarded as the dominant pathogenic species worldwide, but is only one of many streptomycetes which cause very similar disease symptoms on plants. In addition to *Streptomyces scabiei* (Lambert and Loria, 1989b), *Streptomyces acidiscabies* (Lambert and Loria, 1989a), *Streptomyces turgidiscabies* (Miyajima et al., 1998), *Streptomyces europaeiscabiei*, *Streptomyces stelliscabiei* (Bouchek-Mechiche et al., 2000), *Streptomyces luridiscabiei*, *Streptomyces puniciscabiei*, and *Streptomyces niveiscabiei* (Park et al., 2003) have been shown to be plant pathogens that cause either common scab or netted scab, mostly in potatoes.

Streptomyces scabiei (previously know as "*Streptomyces scabies*"), which is the most important and oldest characterized potato scab pathogen, has been isolated from beets, carrot, peanut, and radish, among other crops (Loria et al., 2006). Strains of *Streptomyces scabiei* are phenotypically similar to *Streptomyces bottropensis*, *Streptomyces diastatochromogenes*, and *Streptomyces neyagawaensis*, a result confirmed by 16S rRNA gene sequence analyses. *Streptomyces acidiscabies* has been isolated from low pH soils in the north-eastern United States, amongst other locations. *Streptomyces turgidiscabies* has been isolated from cases of potato scab in Finland, but also from Japan and Korea (Loria et al., 2006). *Streptomyces europaeiscabiei*, the most closely related species to *Streptomyces scabiei* has been isolated from various locations in Europe. Three species, *Streptomyces luridiscabiei*, *Streptomyces niveiscabiei*, and *Streptomyces puniciscabiei*, are the causal agents of potato scab in Korea.

16S rRNA gene sequence analyses and DNA–DNA hybridization studies show that the documented pathogenic strains fall outside the described species listed above (Loria et al., 2006). This can be attributed to the polyphyletic nature of scab-causing species and the existence of a transmissible pathogenicity island, which seems to confer the pathogenic phenotype on some otherwise non-pathogenic species, as reviewed by Loria et al. (2006). The mechanisms used by plant-pathogenic species to manipulate their hosts have been studied in detail and summarized by Loria et al. (2008, 2006). The nitrated dipeptide phytotoxin, thaxtomin, plays an important role in inhibiting cellulose biosynthesis in expanding plant tissues, stimulating Ca^{2+} spiking, and causing cell death. In addition, a secreted necrogenic protein, Nec1, contributes to virulence on diverse plant species. A detailed genetic analysis revealed that the thaxtomin biosynthetic genes and *nec1* lie on a large mobilizable plasmid PAI, along with other putative virulence genes, including a cytokinin biosynthetic pathway and a saponinase homolog. The PAI is mobilized during conjugation and site-specifically inserts itself into the linear chromosome of recipient species, thereby accounting for the emergence of new pathogens in agricultural systems.

Streptomycetes as human pathogens. So far, only very few streptomycetes have been isolated from human pathological material. They include organisms that cause actinomycetoma, which is a localized chronic, destructive, and progressive infection of skin, subcutaneous tissue, and eventually bone (Develoux et al., 1999; McNeil and Brown, 1994). In certain tropical and subtropical regions, this disease is endemic and has a devastating effect on patients, as it frequently leads to deformities, disabilities, and eventually amputation of the affected organs. Although some of the main causal agents belong to other genera and species, i.e. *Actinomadura madurae*, *Actinomadura pelletieri*, *Nocardia brasiliensis*, *Nocardia otitidiscaviarum*, and *Nocardia transvalensis*, *Streptomyces somaliensis* is often implicated, notably in parts of the Sudan (Trujillo and Goodfellow, 2003). However, the recognition of a second species, *Streptomyces sudanensis*, by Quintana et al. (2008) suggests that some strains identified as *Streptomyces somaliensis* (Fahal, 2006; Gumaa, 1994; Gumaa and Mahgoub, 1975; Taha, 1983) may have been misclassified. Indeed, there is evidence that streptomycetes associated with cases of actinomycetoma in the Sudan (Fahal, 2004, 2006; Fahal and Hassan, 1992; Mahgoub, 1985) may be underspeciated (Quintana et al., 2008; Trujillo and Goodfellow, 2003).

Soil as a habitat. Abiotic and biotic factors, especially vegetation, content and kind of organic matter, soil type, season and climate, temperature, circulation of water and air, and pH influence the character and community composition of any habitat, including the microbial community. Streptomycetes are common in soils and have been the subject of several reviews: Goodfellow and Simpson (1987), Korn-Wendisch and Kutzner (1992), Lechevalier (1988), Williams (1982), Williams et al. (1982a). The most extensive studies have been carried out by Stan Williams and his colleagues (Flowers and Williams, 1977a, 1977b; Khan and Williams, 1975; Mayfield et al., 1972; Ruddick and Williams, 1972; Watson and Williams, 1974; Williams et al., 1971; Williams and Mayfield, 1971; Williams and Robinson, 1981). The typical life cycle of streptomycetes in soil, including its genetic control, can be found in Kieser et al. (2000). In most soils, streptomycetes constitute about 1–20% of the total viable count, that is 10^4–10^7 colony-forming units (c.f.u.) per g soil (Korn-Wendisch and Kutzner, 1992), and in some soils form the dominant population. Further details in the numbers and distribution of streptomycetes in soil can be found elsewhere (Flaig and Kutzner, 1960a; Küster, 1976; Misiek, 1955; Szabó and Marton, 1964).

The detection and localization of different *Streptomyces* species in their natural habitat are based mainly on cultivation-dependent techniques. Intrageneric classification of the genus *Streptomyces* is difficult and, hence, ecophysiological studies are often difficult to compare. Williams et al. (1969) assigned soil streptomycetes to color-groups, based on diffusible pigment colors formed on oatmeal agar, and on their capacity to produce melanin pigments on peptone-yeast extract-iron agar. This classification into color-groups was then used as a tool by other researchers to study the diversity of streptomycetes in natural habitats (e.g. Goodfellow and Haynes, 1984; Atalan et al., (2000) Sembiring et al., 2000). However, this color-grouping is a subjective method and comparison of data between different studies is difficult. Recently, a computer-assisted numerical analysis was carried out with 321 alkaliphilic streptomycetes that were assigned to color-groups (Antony-Babu et al., 2010). The authors argue that, with this method, distances between individual colors could be calculated more objectively and that the data can be compared with computer-assisted numerically defined color-groups in future investigations on streptomycete taxonomy in natural habitats.

Williams et al. (1972) have shown that streptomycetes resist desiccation because of their ability to form arthrospores. In addition, the water tension they need for growth can be much lower than for other bacteria, but on the other hand, they may be very sensitive to water-logged conditions.

Most attention has been focused on neutrophilic streptomycetes, which are common in neutral to alkaline soils (e.g. Flaig and Kutzner, 1960a), although acidotolerant and acidophilic streptomycetes are abundant in acidic soils and can be isolated using starch-casein agar adjusted to pH 5.0 supplemented with anti-fungal agents (Hagerdorn, 1976; Khan and Williams, 1975). Acidophilic streptomycetes produce specific and stable amylases (Williams and Flowers, 1978; Williams and Robinson, 1981). In contrast, alkalitolerant and alkaliphilic streptomycetes are common in alkaline soils (Antony-Babu and Goodfellow, 2008; Mikami et al., 1982, 1985; Taber, 1959, 1960).

Streptomycetes, as well as other soil bacteria, have been isolated from the intestinal tract of earthworms (Brüsewitz, 1959; Parle, 1963a, 1963b), the gut of arthropods (Bignell, 1984; Bignell et al., 1980, 1981; Szabó et al., 1967), and pellets produced by millipedes and woodlice (Márialigeti et al., 1984). Streptomycetes are also found in the rhizosphere (Goodfellow and Williams, 1983; Sembiring et al., 2000) where they may have an important role.

It has been suggested ever since the discovery of antibiotics from streptomycetes that antibiotic-producing organisms have a competitive advantage over nonproducing organisms. However, there is no clear evidence for the *in situ* production of antibiotics in soil (Williams, 1982). Antibiotics are difficult to detect in soil as they are found in low concentrations and may be unstable (Brian, 1957; Williams, 1982). In addition, they may be adsorbed onto soil colloids (Williams, 1982) and may also be produced at certain stages of the growth cycle (Williams, 1982; Williams and Khan, 1974).

However, antibiotic production in soil was reported by Rothrock and Gottlieb (1984) who supplemented sterilized soil with nutrients prior to adding a potent producer. In the control of fungal root pathogens, streptomycetes seem to play an important role (Goodfellow et al., 2007; Rothrock and Gottlieb, 1981; Sing and Mehrotra, 1980; Williams, 1978, 1982). It has also been observed that many streptomycetes are often successful in competition with other rhizosphere bacteria such as pseudomonads and bacilli, especially in relatively dry soils.

Thermophilic streptomycetes. The genus *Streptomyces* contains mainly mesophilic species, though some streptomycetes are thermotolerant (growing up to 45°C) and a few are thermophilic. So far, all described thermophilic streptomycetes grow at temperatures between 28–55°C and several grow at even higher temperatures. Kim et al. (1999) studied the taxonomy of thermophilic streptomycetes in detail. Additional thermophilic species (*Streptomyces thermocoprophilus* and *Streptomyces thermospinisporus*) were described by Kim et al. (2000) and Kim and Goodfellow (2002). The life cycle of thermophilic streptomycetes includes active growth at sites of high temperatures, e.g. compost, manure, and self-heating hay or grain. When the vegetative phase ends, the formation of large numbers of spores begins. The spores are returned with the compost or manure to the fields and pastures and can colonize plant material and hay directly or via soil dust (Korn-Wendisch and Kutzner, 1992). Therefore, the genus *Streptomyces* accounts for the majority of actinomycetes isolated from bioaerosols in the surroundings of composting facilities (P. Kämpfer and others, unpublished observation). Thermophilic actinomycetes are widespread and can be isolated from various sources like soils (Craveri and Pagani, 1962; Tendler and Burkholder, 1961), pig feces (Ohta and Ikeda, 1978), sewage-sludge compost (Millner, 1982), and freshwater habitats (Cross, 1981a, 1981b).

Freshwater environments, water supplies, and marine environments. Actinomycetes can easily be isolated from fresh water and especially from sediments of rivers and lakes. However, it is assumed that most of these organisms do not live naturally at these sites and are therefore inactive (Cross, 1981a, 1981b). Instead, they are wash-in forms ("aliens") from surrounding terrestrial environments. In particular, rivers carry vast amounts of various actinomycetes, including streptomycetes. Nevertheless, actinomycetes can survive as dormant spores in aquatic habitats for a long time (Al-Diwany and Cross, 1978). Burman (1973) found 59–200 streptomycetes and 10–20 micromonosporae per ml river water sampled from the River Thames, UK. The streptomycetes grew on decaying vegetation on riverbanks and mud flats at low water or on floating mats of decaying algae or other vegetation. They produce odorous substances which are washed into the water when river levels increase giving rise to "earthy tastes" in drinking water. Geosmin and methyl-isoborneol are the two most frequently detected odorous compounds (Gerber, 1979a, 1979b). Wood et al. (1983) noted that preventing the contamination of potable water with these compounds and, thus, the earthy tastes in reservoirs and water supply systems, depends on locating the production sites and determining the patterns of distribution of these compounds (Lechevalier et al., 1980; Silvey and Roach, 1975). Burman (1973) found that the number of streptomycetes in drinking water was reduced by filtration processes. He also detected a new, aquatic strain of *Streptomyces* in the distribution system (for details, see Burman, 1973).

The occurrence of streptomycetes in marine habitats, including sediments, has been considered by several workers (Cross, 1981b; Goodfellow and Haynes, 1984; Okazaki and Okami,

1976; Weyland, 1981a, 1981b; Weyland and Helmke, 1988). Streptomycetes have been found in the littoral and inshore zone and in deep-sea sediments. Although streptomycetes can be isolated from both localities, they are not necessarily part of the autochthonous microflora, but are probably derived from terrestrial habitats. Streptomycetes isolated from sediments (Roach and Silvey, 1959) and from decaying seaweed (Siebert and Schwartz, 1956) in littoral zones were able to grow on polymeric substances, such as agar and chitin (Humm and Shepard, 1946), alginate and laminarin (Chesters et al., 1956), and cellulose (Chandramohan et al., 1972), which are substances characteristic of these habitats.

In sediments, the ratio of different actinomycete taxa is dependent on the depth and the location of the sampling sites (Weyland, 1981b; Weyland and Helmke, 1988). In the open sea, only low numbers of actinomycetes are generally detected (viable counts about 100 c.f.u. per ml of wet sediment). It is assumed that the distribution of streptomycetes is correlated with barotolerance (Helmke, 1981), halotolerance, and psychrophilism (Weyland, 1981a) (horizontal as well as vertical) of streptomycetes, micromonosporae, and rhodococci. On the other hand, Goodfellow and Haynes (1984) did not find any correlation between salinity, pH, or depth and the number of actinomycetes recovered from marine sediments. These workers studied 732 isolates; 250 belonged to *Streptomyces*, 250 to *Micromonospora*, 140 to *Rhodococcus*, and 92 were assigned to the genus *Thermoactinomyces*. One of the streptomycetes was subsequently identified using a computer-assisted approach (Williams et al., 1983b) and about half of them were assigned to a cluster equated with *Streptomyces albidoflavus* (Williams et al., 1983a).

Streptomycetes are mainly found in sediments of shallow seas (70–520 m deep) with 300–1270 colonies per cm^3, whereas *Micromonospora* are dominant in samples 700–1600 m deep (Okami and Okazaki, 1978). However, these authors did not detect actinomycetes from depths of 2800 and 5000 m in the Pacific Ocean. On the other hand, Pathom-aree et al. (2006) isolated actinomycetes, including streptomycetes, from the Mariana Trench in the Pacific at a depth of 10,898 m. Marine streptomycetes showed a higher salt tolerance than their terrestrial counterparts, though salt tolerance among streptomycetes is widespread (Tresner et al., 1968). A few of the isolated marine streptomycetes were found to be obligate halophiles (Okazaki and Okami, 1976).

Many antibiotic-producing streptomycetes have been isolated from marine habitats (Goodfellow and Fiedler, 2010; Hotta et al., 1980; Okami and Okazaki, 1972; Okami et al., 1976) including seaweed (Nissen, 1963). Recently, Goodfellow and Fiedler (2010) provided a review on a bioprospecting strategy based upon the premise that new secondary metabolites can be found by screening relatively small numbers of dereplicated, novel actinomycetes isolated from marine sediments.

Enrichment, isolation, and cultivation

Korn-Wendisch and Kutzner (1992) summarized extensively the procedures used to isolate streptomycetes. These procedures are briefly described here. Further information about isolation for special purposes, growth, and preservation of streptomycetes can be found in the excellent textbook *Practical Streptomyces Genetics* (Kieser et al., 2000).

Generally, isolation procedures for micro-organisms are dependent on the nature of the micro-organism, as well as the number of individuals relative to the number of other microbes within the habitat (Stolp and Starr, 1981). Direct plating of a serial dilution on a nutrient agar medium can readily lead to a pure culture, if the chosen organism is best adapted to the selected isolation conditions. However, this procedure does not work well for isolation of streptomycetes. Instead enrichment cultures or selective media and/or specific isolation conditions are usually used.

Members of the family *Streptomycetaceae* can be isolated using the following selective criteria (Korn-Wendisch and Kutzner, 1992; Williams et al., 1984a; Williams and Wellington, 1982a, 1982b) (1) choice of the material containing the selected micro-organisms; (2) pretreatment of the sample, and in some cases, enrichment of the chosen microbial groups; (3) use of selective media or selective incubation conditions or both; and (4) colony selection on the basis of colony morphology.

Streptomycetes occur in and can be isolated from a wide variety of habitats. In most cases, the organisms are extracted from soil or another environmental sample, followed by dilution of cells (cell aggregates) to allow cultivation on solid media.

Isolation and enrichment from soil. Vegetative mycelia and spore chains are often closely associated with soil mineral and organic particles. For isolation, vigorous shaking of the sample with the diluent is often needed to suspend the spores or mycelial fragments. It can be helpful to use glass beads and agitate the sample on a shaker. Additional methods are described in the literature, including the use of mechanical devices such as the Ultrasonics sonicator-disrupter, Ultra-Turrax homogenizer, Turmix blender, Waring blender, or a mortar and pestle. However, the efficiency of these pretreatments has not been compared in detail. Other procedures described include the use of chemical disruption methods to separate mycelia from spores. Herron and Wellington (1990) gently shook soil samples with an ion-exchange resin Chelex-100 (Bio-Rad) followed by differential centrifugation and filtration. For increasing the yield and diversity of actinobacteria from natural habitats, the dispersion and differential centrifugation (DDC) technique can be used, which is a multistage procedure that combines several physicochemical treatments (Goodfellow and Fiedler, 2010). The DDC technique was introduced by Hopkins et al. (1991).

Subsequent treatment of samples (i.e. preparing dilutions and plating) differs little from usual bacteriological practice. Before dilutions are made, coarse particles of the soil suspensions should be allowed to settle. Another possibility is the use of the soil particles for the incubation of "soil plates" (Warcup, 1950); this method is also used to isolate fungi. For streptomycetes, the addition of lime to soil can be a helpful enrichment factor [see chapter 2 of Kieser et al. (2000) and references therein]. Surface-inoculation of isolation plates may be carried out with a sterile glass rod (or Drigalski spatula).

To avoid the spread of motile bacteria via water films, plates can be dried at 45°C before incubation (Vickers and Williams, 1987). Another highly recommended procedure is to mix the soil suspension with the molten agar (Korn-Wendisch and Kutzner, 1992). A 100-fold increase in streptomycete colonies on isolation plates can be achieved by the addition of $CaCO_3$ to air-dried soil samples (10:1, w/w) and subsequent incubation at

26°C for 7–9 d in a water-saturated atmosphere (El-Nakeeb and Lechevalier, 1963; Tsao et al., 1960).

Jensen (1930) enriched streptomycetes by amending soil with keratin; it is also known that adding chitin to soil enhances the growth of streptomycetes (Williams and Mayfield, 1971). In addition, enrichment of acidophilic and neutrophilic streptomycetes in acidic soil and litter can be achieved using fungal chitin (Williams and Robinson, 1981). Chitin in the form of insect wings has also been used as an isolation strategy (Jagnow, 1957; Okafor, 1966; Veldkamp, 1955). Other selective isolation methods studied by Porter and Wilhelm (1961) include the use of various other organic materials, such as salmon viscera meal, peanut meal, cottonseed meal, and dried blood flour (15 mg/g of soil), as described by Porter and Wilhelm (1961). Additionally, the authors recorded an increase in the number of streptomycetes (up to 1000-fold) when the enrichment cultures were incubated under moist conditions.

Arginine glycerol agar is frequently used for the selective isolation of streptomycetes (El-Nakeeb and Lechevalier, 1963), as are: HV agar (Hayakawa and Nonomura, 1987a, 1987b), colloidal chitin agar (Hsu and Lockwood, 1975), and reduced arginine starch salts agar.

To reduce or inhibit other microbes, several biological, chemical, and physical methods have been studied (see reviews by: Goodfellow and Williams, 1986; Goodfellow and Fiedler, 2010). The centrifugation of soil suspensions for 20 min at 1600 × *g* separates streptomycetes spores (in the supernatant) from other bacteria and fungal spores (in the sediment) as applied by Nüesch (1965), though this method has not been very successful. El-Nakeeb and Lechevalier (1963) used a similar approach, but obtained a significantly smaller number of streptomycete colonies as compared with the control. A simple sedimentation method was described by Voelskow (1988/89), who suspended 1 g soil in 15 ml salt solution and mixed the preparation by vigorously shaking followed by ultrasonic vibrations. Samples were taken from different levels of this solution after 1, 2, and 4 h of sedimentation, further diluted, and plated onto agar surfaces.

Arthrospores have a relatively high resistance to low moisture tension; hence, initial drying and heating procedures can be applied to environmental samples to reduce the number of unwanted bacteria. A relative increase in streptomycete concentrations can be obtained by drying samples, or by prolonged storage at ambient temperatures for mesophiles and at 50–60°C for thermophiles. A significant reduction in the vegetative bacterial proportion without affecting the colony counts of streptomycetes can be maintained by heat treatment of soil (40–50°C, 2–16 h), as reported by Williams et al. (1972).

Membrane filtration has been used for the enrichment of streptomycetes from water (Burman et al., 1969), and from seawater and mud (Okami and Okazaki, 1972) samples. This method was used as a first step in the isolation of streptomycetes from soil. Trolldenier (1966) filtered 1 ml of a series of 10-fold dilutions through membranes (0.3 µm pore size) prior to placing the latter upside down on a suitable agar medium supplemented with 10% compost soil. Streptomycetes were able to grow through the pores and developed colonies between the agar surface and the membrane filter, whereas other bacteria and fungi were unable to grow through the pores. The application of this procedure led to a three to fivefold increase in the number of streptomycete colonies compared with poured plates without soil in the medium.

The use of cellulose ester membrane filters (pore size 0.01–3.0 µm) was introduced by Hirsch and Christensen (1983). The membrane filters were placed onto nutrient agar containing anti-fungal antibiotics (cycloheximide and candicidin) and samples of soil, water, and vegetable material were used to inoculate the plates. The hyphae of actinomycetes were able to penetrate the pores in the membrane filters and grow on the underlying agar medium after 4 d, whereas the growth of other bacteria was restricted to the surface of the filters. Afterwards, the membrane filters were removed and the plates were reincubated to allow further development of actinomycete colonies. Filters (0.22–0.45 µm) can also be used for the exclusive recovery of actinomycetes, as described by Polsinelli and Mazza (1984) and Hanka et al. (1985).

Several authors have added chemicals to environmental samples to improve isolation efficiency. One recommended method to eliminate bacteria and fungi involved phenol treatment of a dense soil suspension (1.4% for 10 min) though El-Nakeeb and Lechevalier (1963) obtained less favorable results with this method. Burman et al. (1969) found that streptomycetes and other actinomycetes were slightly more resistant to ammonia, chloramine, and sodium hypochlorite than other bacteria. Hence, they used these agents for the treatment of water samples.

Isolation of airborne spores. *Streptomyces* spores from self-heating material such as hay or compost can be agitated in a wind tunnel (Lacey and Dutkiewicz, 1976b) or sedimentation chamber (see below; Lacey and Dutkiewicz, 1976a), prior to using an Andersen sampler to inoculate plates with the resultant aerosol (Goodfellow and Williams, 1986). This method is widely employed for the isolation of thermophilic actinomycetes, but can also be used for the isolation of mesophilic streptomycetes from soil. Other devices such as filtration samplers (e.g. Sartorius MD 8) can be used for the sampling of airborne streptomycetes.

Use of selective media. For the isolation of desired micro-organisms, selective media are widely used. By varying a number of factors, the media are favorable for some microbes but not for others. Factors that can be varied are as follows: (1) the nutrient composition and concentration of the isolation medium can be adjusted to the preferred micro-organisms, i.e. choice of carbon and nitrogen sources preferred by the organisms; (2) chemical substances can be added to the medium to inhibit selectively the accompanying flora of the natural habitat or to stimulate the desired organisms; (3) adequate pH values for acidophilic, neutrophilic, and alkaliphilic organisms can be chosen; (4) various temperatures can be used, depending on the temperature optima of the organisms, e.g. thermophiles or psychrophiles.

For the isolation of streptomycetes, many different media have been empirically formulated. In Table 265, selected carbon and nitrogen compounds are listed that are especially suitable for the isolation of these organisms. Table 266 and Table 267 list the most frequently used media with their formulae. On the other hand, streptomycetes can also be grown on very poor media such as water agar.

Different carbon and nitrogen sources for enrichment. It was recognized early on that streptomycetes can degrade chitin (Jagnow, 1957; Veldkamp, 1955). On this basis, Lingappa and Lockwood (1962) described a chitin medium for selective

TABLE 265. Nutrients and selective agents recommended for isolation of streptomycetes from soil (according to Korn-Wendisch and Kutzner, 1992)

	Selective agents in the medium		
Preferred C and N source	Antibiotic	Others	Reference
Starch, KNO_3			Flaig and Kutzner (1960a)
Starch, casein, KNO_3			Küster and Williams (1964a)
Chitin			Lingappa and Lockwood (1962)
Glycerol, arginine			El-Nakeeb and Lechevalier (1963)
Glycerol, casein, KNO_3			Küster and Williams (1964a)
Raffinose, histidine			Vickers et al. (1984)
Starch, casein, KNO_3	Rifampin		Vickers et al. (1984)
Starch, casein, KNO_3	Cycloheximide, nystatin, penicillin, polymyxin		Williams and Davies (1965)

[b]Alternatively, glycerol at 10 g/l can be used.

[c]Not contained in the dehydrated medium; added at the time of preparation.

[d]The different amounts of the agar are due to the varying quality used by the individual authors.

TABLE 267. Composition of some media suitable for the cultivation of streptomycetes (according to Korn-Wendisch and Kutzner, 1992)[a]

Medium	Ingredients	Comments
1. Glucose-yeast extract-malt extract (GYM) agar	Glucose, 4.0 g	Addition of $CaCO_3$, 2.0 g/liter, is advantageous for streptomycetes. Adjust medium to pH 7.2
	Yeast extract, 4.0 g	
	Malt extract, 10.0 g	
	Agar, 12.0 g	
	Distilled water, 1 l	
2. Oatmeal agar	Oatmeal, 20.0 g	Cook 20.0 g oatmeal in 1 liter distilled water for 20 min. Filter through cheesecloth. Add distilled water to restore volume of filtrate to 1 liter, then add trace salts solution and agar. Adjust to pH 7.2.
	Agar, 12.0 g	
	Trace salts solution (see no. 5), 1.0 ml	
	Distilled water, 1 l	
3. Inorganic salts-starch agar	Starch (soluble), 10.0 g	Make a paste of the starch with a small amount of cold distilled water and bring to a volume of 1 liter; then add the other ingredients. The pH should be between 7.0 and 7.4. Do not adjust it if it is within this range.
	$(NH_4)_2SO_4$, 2.0 g	
	K_2HPO_4 (anhydrous basis), 1.0 g	
	$MgSO_4 \cdot 7H_2O$, 1.0 g	
	NaCl, 1.0 g	
	$CaCO_3$, 2.0 g	
	Trace salts solution (see no. 5), 1.0 ml	
	Agar, 12.0 g	
	Distilled water, 1 l	
4. Glycerol-asparagine agar	Glycerol, 10.0 g	The pH should be about 7.0–7.4. Do not adjust if it is within this range
	L-Asparagine (anhydrous basis), 1.0 g	
	K_2HPO_4, 1.0 g	
	Trace salts solution (see no. 5), 1.0 ml	
	Agar, 12.0 g	
	Distilled water, 1 l	
5. Trace salts solution	$FeSO_4 \cdot 7H_2O$, 0.1 g	
	$MnCl_2 \cdot 4H_2O$, 0.1 g	
	$ZnSO_4 \cdot 7H_2O$, 0.1 g	
	Distilled water, 100.0 ml	
6. Trace elements solution SPV-4	$CaCl_2 \cdot 2H_2O$, 4.0 g	SPV-4 is used as an alternative to (5). 5 ml of this stock solution is added to 1 liter of medium
	Fe (III) citrate, 1.0 g	
	$MnSO_4$, 0.2 g	
	$ZnCl_2$, 0.1 g	
	$CuSO_4 \cdot 5H_2O$, 0.04 g	
	$CoCl_2$, 0.022 g	
	$Na_2MoO_4 \cdot 2H_2O$, 0.025 g	
	$Na_2B_4O_7 \cdot 10H_2O$, 0.1 g	
	Distilled water, 1 l	

[a]Recipes 1–5 are from Shirling and Gottlieb (1966) and recipe 6 is from Voelskow (1988/89).

isolation. However, this chitin medium was only a little better than water agar, which was recognized by the authors and later also by El-Nakeeb and Lechevalier (1963). A useful medium for the isolation of actinomycetes (*Streptomyces*, *Nocardia*, and *Micromonospora*) from water samples was developed by Hsu and Lockwood (1975), who added mineral salts to the chitin medium (Table 266). Unfortunately, it had little effect when isolating actinomycetes from soil. Note that chitinolytic activity is not a genus-specific feature for *Streptomyces*. Only 25% of over 300 strains were strongly chitinolytic (Williams et al., 1983a). Consequently, this widely used medium selects chitinolytic streptomycete strains which may not be the most abundant in soil. Starch is a suitable selective carbon source for streptomycetes, as it is degraded by the vast majority of streptomycetes. The combination of starch with nitrate is used by many streptomycetes in contrast to other bacteria (Flaig and Kutzner, 1960a). Küster and Williams (1964a, 1964b), who improved this medium, stated: "The three best media, allowing good development of streptomycetes while suppressing bacterial growth, were those containing starch or glycerol as the carbon source with casein, arginine, or nitrate as the nitrogen source." Streptomycete isolation is also favored by the combination of

glycerol and arginine (Benedict et al., 1955). Further studies by El-Nakeeb and Lechevalier (1963) revealed that this medium (Table 266 and Table 267) was superior to nine other media, resulting in higher numbers and proportions of streptomycete colonies.

Other compounds that have been used successfully for the selective isolation of streptomycetes are, e.g. cholesterol (Brown and Peterson, 1966), elemental sulfur (Wieringa, 1966), pectin (Wieringa, 1955), poly-β-hydroxybutyrate (Delafield et al., 1965), rubber (Nette et al., 1959), and natural and artificial humic acids (Hayakawa and Nonomura, 1987a, 1987b). Most of these compounds strongly select organisms which produce visible zones of clearing or other changes in the medium.

Compounds with anti-fungal activity (antibiotics) are generally used to supplement isolation media to suppress fungal growth (Table 265), notably, cycloheximide (actidione, 50–100 μg/ml), as described by Williams and Davies (1965). Additionally, these authors found that pimaricin and nystatin (each at 10–50 μg/ml) were even more effective.

Compounds with anti-bacterial activity need to be used with care as some actinomycetes may also be sensitive to them. Polymyxin (5 μg/ml) and penicillin (1 μg/ml), for instance, suppress the growth of bacteria, but also inhibit some streptomycetes (Williams and Davies, 1965). Actinobacterial genera differ significantly in their sensitivity to anti-bacterial compounds, notably streptomycetes (Preobrazhenskaya et al., 1978). Thus, it may be more helpful to use anti-bacterial compounds for the isolation of other actinobacterial genera (Cross, 1982).

However, the selective isolation of certain species or groups of *Streptomyces* can be facilitated by supplementary media with antibiotics, as exemplified by the use of starch-casein agar containing rifampin (50 μg/ml) for the selective isolation of members of the *Streptomyces diastaticus* cluster by Williams et al. (1983a) and Vickers et al. (1984). A similar effect was described by Wellington et al. (1987), who used several media containing different C and N sources, as well as media supplemented with inhibitors.

Streptoverticil-producing *Streptomyces* species were isolated by Hanka et al. (1985) using a selective isolation medium supplemented with cycloheximide and nystatin (each at 50 μg/ml), to control fungal growth, and oxytetracycline (25 μg/ml) to suppress that of other actinomycete genera, including *Streptomyces* groups. By adding lysozyme (1000 μg/ml), Hanka and Schaadt (1988) enhanced the selectivity of this medium. The selectivity of this medium was enhanced by the addition of sodium propionate to suppress the growth of fungi (Crook et al., 1950; Table 265). Starch-casein-nitrate agar (Ottow, 1972) containing Rose Bengal (35 mg/l) suppresses the growth of most bacteria and inhibits spreading of fungi across isolation plates.

pH of isolation media and incubation temperatures. Most streptomycetes grow optimally at neutral pH values, i.e. they are neutrophilic organisms. Consequently, most isolation media have pH values of 7.0–7.5. In contrast, acidophilic streptomycetes grow best on media with a pH of 4.5 (Khan and Williams, 1975) and alkaliphilic strains show optimum growth on media with pH values of 10–11 (Mikami et al., 1982). Most streptomycetes isolated from soils are mesophilic; hence, isolation plates are usually incubated at 22–37°C (mostly at 28°C). In contrast, psychrophilic strains (e.g. from marine environments) grow best at 15–20°C, while thermotolerant and thermophilic strains grow well at higher temperatures (40, 45, 50, or 55°C). Thermophilic actinomycetes often form colonies within 2–5 d of incubation, whereas their mesophilic counterparts tend to produce visible colonies within 7–14 d. Marine and other psychrophilic actinomycetes may need several weeks (up to 10) for visible colonies to appear on isolation media.

In most cases, colonies of *Streptomyces* can be readily recognized by their macroscopic and microscopic appearance. *Streptomyces* can usually be purified by transferring colonies from isolation plates into nonselective medium. Williams and Wellington (1982b) stated that purification is "undoubtedly the most time-consuming and often the most frustrating stage of the isolation procedure". Acidiphilic streptomycetes can be readily isolated on acidified starch-casein agar supplemented with cycloheximide and nystatin (Kim et al., 2003b).

Isolation of antibiotic-producing actinomycetes. Antibiotic-producing streptomycetes are isolated following the same procedures as given above.

The activity of streptomycetes is normally tested after the isolation of pure cultures, though procedures are available to detect them on isolation plates. Antibiotic exhibiting strains can, for instance, be detected on initial dilution plates by flooding or spraying them with appropriate indicator organisms then incubating plates until zones of inhibition are detected (Lindner and Wallhausser, 1955; Wilde, 1964). Alternatively, antibiotic activity of the colonies against selected sensitive organisms can be examined by using a simple replication procedure (Lechevalier and Corke, 1953). Further information about selective techniques that can be used for the isolation and screening of antibiotic producing actinomycetes can be found in Nolan and Cross (1988). Protocols for the selective isolation of streptomycetes for the generation of spore suspensions and for more sophisticated experimental procedures are described by Kieser et al. (2000).

Isolation of thermophilic streptomycetes. As stated earlier, most actinomycetes, including thermophilic streptomycetes, originate from samples taken from high temperature environments (e.g. compost materials, manure heaps, and fodders). Consequently, high temperatures (45–60°C) should be used for the selective isolation of such organisms (Festenstein et al., 1965).

It is also important to incubate thermophilic streptomycetes in a humid atmosphere (Greiner-Mai et al., 1987) by incubating plates in large jars with water at the bottom; another effective method is to seal Petri dishes with masking tape.

Interestingly, the media recommended for the isolation of thermophilic actinomycetes, including streptomycetes, contain higher nutrient concentrations than those used for mesophilic strains. Sometimes, anti-fungal and anti-bacterial agents are added as supplements to such media (Goodfellow et al., 1987b; Lacey and Dutkiewicz, 1976b). Special procedures recommended for the isolation of thermophilic actinomycetes are available (Cross, 1968; Fergus, 1964; Gregory and Lacey, 1963; B. Kim et al., 2000; D. Kim et al., 1996; S.B. Kim et al., 1998; Uridil and Tetrault, 1959).

Isolation from aquatic habitats. The media listed in Table 266 can be used to isolate streptomycetes from water. Hsu and Lockwood (1975) found that chitin-agar was more effective than egg albumin, glycerol-arginine, starch-casein, and *Actinomyces* isolation agars for the incubation of actinomycetes from aquatic habitats (see also Table 266).

After dilution, water samples can be streaked directly onto solid medium. When low numbers of actinomycete samples are expected, they can be concentrated by membrane filtration [for details, see Burman et al. (1969)].

The selective isolation of streptomycetes from marine habitats can be enhanced when media are prepared using seawater or an equivalent. Media containing 25 or 75% seawater (Weyland, 1981a, 1981b), artificial seawater (Goodfellow and Haynes, 1984), and deionized water supplemented with 3.0% NaCl (Okami and Okazaki, 1978) have all proved to be effective. See Weyland (1981b) and Goodfellow and Haynes (1984) for further details.

Isolation from diseased plants. For the isolation of streptomycetes from diseased plant tissues, e.g. scabby potatoes or beet surface layers, three general steps have been recommended (see also Korn-Wendisch and Kutzner, 1992): sterilization of the surfaces of tubers, beets, or roots; maceration of plant tissues; and use of appropriate isolation media. Several authors have described detailed methods for the isolation of *Streptomyces scabiei* from potatoes (Adams and Lapwood, 1978; Archuleta and Easton, 1981; KenKnight and Munzie, 1939; Menzies and Dade, 1959; Taylor, 1936).

Nutritional requirements and media for sporulation. The vast majority of streptomycetes are nonfastidious organisms with a chemo-organotrophic metabolism. The nutritional requirements of streptomycetes are appropriate to an organic carbon source, such as starch, glucose, glycerol, and lactate, and usually met by the provision of a suitable inorganic nitrogen source, like ammonium or nitrate (Kutzner, 1981). However, different isolates can vary considerably in their carbon and nitrogen source utilization patterns, which are often used as taxonomic characters (e.g. Shirling and Gottlieb, 1966; Pridham and Tresner, 1974a; Williams et al., 1983a; Kämpfer et al., 1991). Widely used carbon sources include cellobiose, glucose, glycerol, D-mannose, and trehalose; useful nitrogen sources are ammonium, L-arginine, L-asparagine, and nitrate. Relatively few strains use organic acids, inulin, L-methionine, nitrite, or xylitol, but most can degrade casein, esculin, gelatin, and hypoxanthine. Streptomycetes grow well on many different media, but spore production is usually most prolific on those with a high carbon:nitrogen ratio (Kutzner, 1981). Streptomycetes generally require a good supply of free water for growth, but are unable to develop at high osmotic or matric potentials. Survival of streptomycetes in dry conditions is aided by the high resistance of arthrospores, in contrast to vegetative mycelia, to desiccation (Williams et al., 1972).

The need to add specific trace elements to culture media has not been studied in detail. Spicher (1955) described the positive effect of trace elements in soil on the growth of streptomycetes. However, many of the early media used (even the "synthetic" media) were not supplemented with trace elements. Indeed, recipes of many authors (Table 266 and Table 267) contained only a selected number of metal ions. A rather complete mixture (SPV-4; Table 267) has been found to be optimal for the growth of actinomycetes and other bacteria (Voelskow, 1988/89).

"Synthetic media" can be used for the cultivation of streptomycetes, though the need for specific nutritional requirements with respect to vitamins and organic growth factors has not been addressed. Growth rates and biomass production can be enhanced by using complex organic substrates (e.g. malt extract, oatmeal, or yeast extract). A combination of a complex organic carbon source with a single amino acid as nitrogen source (e.g. glutamic acid, arginine, or asparagine) is also suitable.

"General media" have been proposed for the growth of streptomycetes as they allow the completion of the *Streptomyces* life cycle, i.e. germination of spores, growth of substrate and aerial mycelium, and visible formation of spores (visible, because of the typical color of the spores). Some of these media were used in the International *Streptomyces* Project (ISP), among them glucose-yeast extract-malt extract, oatmeal, inorganic salts-starch, and glycerol-asparagine agars (Shirling and Gottlieb, 1966). Innumerable general media have been recommended for the growth of streptomycetes, four of which are of considerable practical value (Table 267). For additional media formulations, see Waksman (1961) and Williams and Cross (1971). $CaCO_3$ is added to some media, as Ca^{2+} promotes growth and neutralizes acids produced by many streptomycetes; such media also allow good sporulation. Cultures should be checked microscopically to detect the extent of sporulation as macroscopically heavy aerial mycelia may contain very few spores while aerial mycelia which are hardly detectable by the naked eye may be a good source of spores.

A list of specialized media especially for genetic studies on streptomycetes is given by Kieser et al. (2000).

Media containing soil, clay, minerals, and calcium humate. Soil promotes growth, sporulation, and pigmentation of actinomycetes/streptomycetes (Trolldenier, 1966) and is therefore often added to isolation media to increase the number of colonies. The addition of montmorillonite or calcium humate to liquid media stimulates the growth and metabolic activity of some actinomycetes (Martin et al., 1976). A similar effect has been observed for clay in dialysis tubes after a short lag period, an observation which may be explained by the adsorption of one or more inhibitory substances produced during growth. Adsorbing materials have a positive effect on the genetic stability of other bacteria and on fungi (Martin et al., 1976).

Temperature, pH, and oxygen. The environmental requirements and tolerances of streptomycetes have been described in detail by Kutzner (1981). Most streptomycetes grow at temperatures between 10 and 37°C and, hence, are regarded as mesophiles. Nevertheless, several species can grow at temperatures above 37°C, although most of them are thermotolerant rather than thermophilic in their responses. A variety of type strains studied by Williams et al. (1983a) grew at 10, 37, and 45°C, although a few grew slowly at 4°C (1983a). However, in many instances, the optimal temperature for rapid growth or maximal yield may not be the best choice for studying the production of secondary metabolites (e.g. antibiotics and pigments). This means that culture conditions are influenced by the aims of the study.

Most *Streptomyces* strains behave as neutrophiles in culture, growing between pH 5.0 and 9.0, with an optimum close to pH 7.0. Only a few of the type strains studied by Williams et al. (1983a) were able to grow at pH 4.3, though large populations of acidophilic and acidoduric strains have been reported from acidic soils (Hagedorn, 1976; Khan and Williams, 1975; Williams et al., 1971). Acidophilic streptomycetes grow from about

pH 3.5 to 6.5, and optimally between pH 4.5–5.5. However, a wide spectrum of pH requirements exists among streptomycetes from acidic environments (Flowers and Williams, 1977b). Acidophilic strains are able to produce diastases (Williams and Flowers, 1978) and chitinases which have optima pH below that of corresponding enzymes from neutrophilic counterparts.

Populations of alkaliphilic streptomycetes with optimal growth at pH 9.0–9.5 have been isolated from soils in Japan by Mikami et al. (1982), who found that six of the type strains tested were able to grow at pH 11.5.

In addition, large populations of alkaliphilic streptomycetes have been isolated from a beach and dune sand system at Ross Links in Northumberland, UK (Antony-Babu and Goodfellow, 2008). Streptomycetes are generally regarded as obligate aerobes with a limited capacity for microaerophilic growth in culture (Kutzner, 1981) and dissimilatory reduction of nitrate is common. Whether streptomycetes grow aerobically or microaerophilically depends on the nutritional status of the medium.

In a nutrient medium, streptomycetes grow aerobically at the surface of the semisolid agar column, but in poor media or in a medium with a non-utilizable carbon source, they grow microaerophilically in semisolid agar. In stationary liquid culture, streptomycetes grow as pellicles at the surface, while the medium itself remains completely clear.

Cultivation and preparation of inoculum. Solid media in dishes or slants should be used for the growth of streptomycetes for subcultivation and maintenance as well as for most diagnostic tests. Many strains produce aerial mycelia and spores on solid media when the entire surface is covered by confluent growth. In contrast to most molds, *Streptomyces* colonies spread over a limited distance and, hence, a point inoculation will not usually lead result in confluent growth. However, if streaked onto a plate, some strains need empty spaces between the streaks (cross-hatch inoculation) to sporulate. Dry conditions are generally more suitable for sporulation. A horizontal incubation of slants for the first 2 d allows liquid to soak into the surface of the agar (Hopwood et al., 1985). A suspension of inoculum in liquid should be used as starting material for sporulation (Kieser et al., 2000).

For the propagation of cultures, single colonies should be selected and streaked onto fresh media. Successive rounds of mass culture should be avoided, especially in genetic studies, because this technique reduces the accumulation of revertants or the gradual loss of selected plasmids or both (Kieser et al., 2000). When streptomycetes are cultivated on solid media, morphological heterogeneity is often observed. More details can be found in Kieser et al. (2000).

Precultivation of grown colonies in liquid media is required to obtain a homogeneous suspension for some diagnostic tests (Kämpfer et al., 1991). Streptomycetes should be cultivated in liquid medium without agitation. This precultivation is necessary for certain physiological studies (e.g. degradation tests), for the provision of cell material for biochemical analysis, and for the production of secondary metabolites (e.g. antibiotics) or enzymes. For many detailed studies, e.g. for preparation of protoplasts for fusion, transformation or transfection, liquid cultures should also be started from an inoculum of spores.

The multicellular lifestyle of streptomycetes causes some problems in the study of metabolic properties because not all cells of the initial suspension are in the same physiological condition. In general, streptomycetes grow by mycelial elongation and branching. However, physiological homogeneity cannot be sustained when central parts of the colony become nutrient limited. Therefore, spore germlings are used in physiological studies, although large numbers of spores are needed. To avoid this problem, liquid cultures can be supplemented with, for example, dispersants, like agar, carboxymethylcellulose, Junlon, polyethylene glycol, starch, and sucrose. A summary of the advantages and disadvantages of these methods can be found in chapter 2 of Kieser et al. (2000). Cultures need to be shaken during incubation due to the highly aerobic nature of streptomycetes. Recommended procedures include Erlenmeyer flasks with the use of indentations or stainless steel springs, but tubes in a slanted position on a shaker or roller also allow an excellent supply of oxygen for small quantities of broth, 3–5 ml being enough for some physiological tests. However, it should be noted that some secondary metabolites (e.g. antibiotics and pigments, which are produced on solid media) may not be synthesized under these conditions.

Two media recommended by Korn-Wendisch and Kutzner (1992) have been widely used for submerged cultivation of streptomycetes (g/l): 1) GPYB broth (glucose, 10.0; peptone from casein, 5.0; yeast extract, 5.0; beef extract, 5.0; $CaCl_2 \cdot 2H_2O$, 0.74; pH 7.2); and 2) soybean meal-mannitol nutrient medium (soybean meal, 20.0; mannitol, 20.0; pH 7.2). Arthrospores and vegetative mycelium can be used as inoculation material for subculturing streptomycetes; vegetative mycelium occasionally includes "submerged spores" (Wilkin and Rhodes, 1955). Similar procedures are recommended by Kieser et al. (2000).

Spore suspensions stored at 4°C can be used for several weeks. A few glass beads should be added to the screw-cap tubes, as spores tend to settle and clump. Glass beads help to resuspend spores before use. The preparation of mycelia for detailed DNA or RNA studies is described in chapters 8 and 9 of Kieser et al. (2000).

Maintenance procedures

Several different procedures have been employed (Kirsop and Snell, 1984) for the short- and long-term preservation of microorganisms. Korn-Wendisch and Kutzner (1992) described three short-term preservation methods: (1) agar slope cultures may be stored at 4°C for few months; (2) spore suspensions can be mixed with soft water agar and kept at 4°C (Kutzner, 1972); and (3) glycerol can be added to spore suspensions (final concentration, 10%, v/v) which are then stored at −20°C (Wellington and Williams, 1978). After thawing, these cultures can serve as inocula for most diagnostic tests, except carbon utilization (Williams et al., 1983a).

For long-term preservation, Kieser et al. (2000) recommended the preparation of spore suspensions in 20% glycerol which can be frozen and maintained at −20°C. In another method, strains are grown in complex media like trypticase soy broth (TSB) agar, 20% glycerol plus 10% lactose are added, and the samples are stored in the vapor phase of liquid nitrogen. A third method uses drying on unglazed porcelain beads (Lange and Boyd, 1968), followed by soil culture (Pridham et al., 1973), and lyophilization (Hopwood and Ferguson, 1969).

Spore suspensions or homogenized mycelia mixed with glycerol to give a final concentration of 25% can be kept at −25°C

for longer term preservation (Wellington and Williams, 1978). Alternatively, spores and mycelia suspended in 10% skim milk can be lyophilized. Liquid nitrogen cryopreservation is a very simple, reliable, and time-saving method. In this method, living cells are stored in small polyvinyl chloride (PVC) tubes ("straws") at −196°C; this procedure has been tested for various actinomycetes. First, strains are harvested from well-sporulated cultures grown on suitable agar media in Petri dishes. A 2 × 25 mm piece of sterile PVC tubing is pressed into the mycelial mat and agar, and carefully raised to excise the agar plug. This procedure is repeated until the tube is filled with agar. The tube is then placed in a sterile cryovial (the screw cap marked with the strain accession number); up to 13 tubes can be placed in a 1.8 ml vial. Two vials prepared for each strain are then fixed to a metal clamp for freezing in the gas phase of a liquid nitrogen container. After 10–15 min, when the temperature falls below −130°C, the clamp can be immersed in the liquid phase at −196°C. A container with a capacity of 250 l will hold at least 8000 vials or 4000 strains. For viability testing, one tube is removed from the vial within the nitrogen gas atmosphere of the container and placed directly and thawed on a suitable agar medium. The mycelium will be visible after a few days of incubation. Plugs may be pushed out of the tubes with a sterile needle when strains do not produce abundant mycelium.

Differentiation of the genus *Streptomyces* from other genera

It is standard practice to assign unknown actinomycetes to genera based on 16S rRNA gene sequence analyses. However, it can be difficult to distinguish between species using this approach, especially in the case of streptomycetes (e.g. Stackebrandt et al., 1991a, 1991b, 1992); Kumar and Goodfellow, 2008).

Members of the genus *Streptomyces* can often be distinguished from other filamentous actinomycetes on the basis of colony morphology (Table 268 and Table 269), in particular by aerial spore mass substrate mycelium and soluble pigment colors. Traditional methods highly recommended for this purpose are described by Korn-Wendisch and Kutzner (1992). Antony-Babu et al. (2010) used a computer-assisted numerical analysis based on the color-grouping procedure of Williams et al. (1969) to group 321 alkaliphilic streptomycetes grown on oatmeal agar (ISP 3) and peptone-yeast extract-iron agar (ISP 6). With this method, large numbers of streptomycetes can be assigned without using polyphasic taxonomic approaches.

In addition, streptomycetes can often be distinguished from other filamentous actinomycetes on the basis of morphological properties, notably aerial mycelium, arthrospores, and vegetative mycelium (Figure 357, Figure 358, and Figure 359). Details on the procedure used to detect such properties can be found in Korn-Wendisch and Kutzner (1992) and chapter 3 of Kieser et al. (2000).

Members of the genus *Streptomyces* can also be distinguished from related taxa using chemotaxonomic procedures (Lechevalier and Lechevalier, 1970b). Streptomycetes typically contain LL-A_2pm in cell wall or whole-cell hydrolysates (Lechevalier and Lechevalier, 1970b, 1970c), they lack mycolic acids, and produce major amounts of iso- and anteiso-methyl branched fatty acids (Kroppenstedt, 1985) (Table 263). Major menaquinones are hexa- and octa-hydrogenated menaquinones with nine isoprene units (Kim et al., 2003b). An important chemotaxonomic character for the differentiation of *Kitasatospora* from *Streptomyces*

TABLE 268. Spore colors for the grouping of streptomycetes and representatives of each color group (according to Korn-Wendisch and Kutzner, 1992)

Color of aerial mycelium	Representative species (DSM no.)[a]
Yellow-gray: "griseus"	*S. griseus* (40236); *S. coelicolor* (40233)
Pink/light violet	*S. fradiae* (40063); *S. toxytricini* (40178)
Gray-pink/lavender: "cinnamomeus"	*S. lavendulae* (40069); *flavotricini* (40152)
Brown (plus gray or red)	*S. eurythermus* (40014); *S. fragilis* (40044)
Blue: "azureus"	*S. viridochromogenes* (40110); *S. cyaneus* (40108)
Blue-green: "glaucus"	*S. glaucescens* (40155)
Green: "prasinus"	*S. prasinus* (40099); *S. hirsutus* (40095)
Gray: "cinereus"	*S. violaceoruber* (40049); *S. echinatus* (40013)
White: "niveus"	*S. albus* (40313); *S. longisporus* (40166)
Not definable: white plus various plus various light-colored shades	*S. alboniger* (40043); *S. rimosus* (40260)

is the presence of *meso*-A_2pm in whole-cell hydrolysates (Table 263). In *Kitasatospora* strains, the *meso*-A_2pm content is 49–89%, whereas in *Streptomyces* strains it is 1–16% (Zhang et al., 1997). The predominant diamino acid of strains belonging to the genus *Streptacidiphilus* is (like *Streptomyces*) LL-A_2pm (Kim et al., 2003b). Further useful characters for species identification are shown in Table 274.

Taxonomic comments

Phenotypic methods comprise all procedures that are not directed towards analyses of DNA or RNA, and include chemotaxonomic techniques. Most early studies on streptomycetes (between 1916 and 1943) were carried out by soil microbiologists who were mainly interested in ecological questions; hence, only a few species were described at that time. Descriptions were mainly based on morphological criteria, pigmentation, and ecological requirements (Jensen, 1930; Waksman, 1919; Waksman and Curtis, 1916). However, the discovery of actinomycin from *Streptomyces antibioticus* (Waksman and Woodruff, 1940) promoted widespread interest in streptomycetes as a source of novel bioactive compounds. The focus on screening streptomycetes for novel bioactive compounds led to a widespread tendency for streptomycetes to be assigned to novel species on the basis of their ability to produce new natural products. This tendency led to an explosion of species descriptions and resulted in an overclassification of the genus with over 3000 species being recognized (Trejo, 1970).

The International *Streptomyces* Project (ISP) introduced 1964 standard criteria for determining species (Shirling and Gottlieb, 1968a, 1968b, 1969, 1972). These descriptions were based mainly on morphology (i.e. spore chain arrangement, spore surface ornamentation, color of spores, substrate mycelium, soluble pigments, and production of melanin pigments), and a few physiological properties, which were mainly restricted to utilization tests of different carbon sources. As a result, more than 450 *Streptomyces* species were redescribed and their type strains were deposited in internationally recognized culture collections. However, these studies did not directly lead to the generation of schemes for the identification of *Streptomyces* species.

Numerical taxonomic methods were developed in the 1960s for both the classification and identification of bacteria, including streptomycetes. Silvestri et al. (1962) carried out the first numerical taxonomic studies on streptomycetes and found considerable diversity within the genus, as well as groups which corresponded to initial morphological descriptions. However, these studies had little impact on *Streptomyces* systematics and did not

TABLE 270. Numerical classifications of streptomycetes (modified according to Korn-Wendisch and Kutzner, 1992)

Number of strains	No. characters (features)	Nature of material	No. clusters	No. unclustered strains	Reference
159	105	"Species"	24	16	Silvestri et al. (1962)
18	46	Isolates	5		Williams et al. (1969)
448	31	ISP "species"	14/21	168/37	Kurylowicz et al. (1967)[a]
618	24	ISP "species"	15	218	Gyllenberg (1976)
111	185	*Streptomyces* with verticals and pseudoverticils, formerly *Streptoverticillium*	24		Locci et al. (1981)
475	139	394 ISP species plus others	73	28	Williams et al. (1983a)
821	329	394 ISP species plus others	15 (major), 34 (minor)	40	Kämpfer et al. (1991)

[a]14 and 168 were obtained by the Wroclaw dendrite method. 21 and 37 were obtained by the centrifugal correlation method.

result in any nomenclatural changes, despite the development of other small databases for the identification of streptomycetes (Kurylowicz et al., 1975; Gyllenberg, 1976; Table 270).

A large-scale numerical taxonomic study was undertaken by Williams et al. (1983a) who analyzed 475 strains (including 394 *Streptomyces* type cultures from the ISP) for 139 unit characters using the simple matching (S_{SM}) and Jaccard coefficients (Sj), and the mean linkage algorithm UPGMA (unweighted pair group method with arithmetic means). The 394 type strains were assigned to 19 major (6–71 strains), 40 minor (2–5 strains), and 18 single clusters recovered at the 77±5% S_{SM} level. The minor and single-membered clusters were equated with species and the major clusters with species-groups.

The largest species group, *Streptomyces albidoflavus* (cluster 1), contained 71 strains, including 44 type strains, 15 representatives of species with names that were not validly published, and 12 unnamed strains. This taxon was subsequently subdivided into three subclusters: cluster 1a, *Streptomyces albidoflavus* subsp. *albidoflavus* (20 strains); cluster 1b, *Streptomyces albidoflavus* subsp. *anulatus* (38 strains); and cluster 1c, *Streptomyces albidoflavus* subsp. *halstedii* (13 strains; Williams et al., 1989). Cluster 1 included strains which showed considerable phenotypic diversity, though almost all of the strains formed yellow gray colonies, smooth spores in straight chains, did not produce melanin pigments, and were resistant to several antibiotics, including cephaloridine, lincomycin, and penicillin. Nearly 40% of the strains produced compounds with anti-fungal activity, 32% of the compounds were active against Gram-stain-positive micro-organisms, and 10% inhibited Gram-stain-negative micro-organisms (Williams et al., 1983b). This example highlights the extensive diversity found within a single cluster and exemplifies problems associated with streptomycete systematics (Anderson and Wellington, 2001).

The comprehensive survey of Williams et al. (1983a) led to a reduction in the number of described *Streptomyces* species (Williams et al., 1989), although the problem of overspeciation remained. Additionally, isolates from natural habitats did not match the reference strains used to construct identification schemes (Goodfellow and Dickenson, 1985). The problem was addressed by the generation of probability matrices for the identification of streptomycetes (Langham et al., 1989; Williams et al., 1983b), but these developments were not widely adopted by the scientific community.

The chapter on *Streptomyces* in the 1989 edition of *Bergey's Manual of Systematic Bacteriology* (Williams et al., 1989) was based on the numerical taxonomy studies of Williams and his colleagues. This chapter included descriptions of 142 *Streptomyces* species, in contrast to the 463 species described in the 1974 edition of *Bergey's Manual of Determinative Bacteriology* (Pridham and Tresner, 1974a).

Kämpfer et al. (1991) carried out an extensive numerical taxonomic analysis of the genus *Streptomyces* and, where possible, included more than one strain of each species. These workers examined 821 strains for 329 physiological properties and compared their data with those of Williams et al. (1983a). They also examined their strains for genetic and chemotaxonomic properties and compared them with the numerical data. They recognized many of the clusters defined by Williams et al. (1983a); for example, the *Streptomyces albidoflavus*, *Streptomyces anulatus*, *Streptomyces griseus*, and *Streptomyces halstedii* groups were recovered in both studies; 28 of the *Streptomyces griseus* strains were assigned to cluster 1. Interestingly, groups often contained strains which shared the same specific epithet indicating that some previous classifications were reliable. However, exceptions were also observed, for example, *Streptomyces hygroscopicus* strains were recovered in cluster 1 and in several other clusters and subclusters.

Data generated in this study were used to construct a probability matrix for the identification of streptomycetes (Kämpfer and Kroppenstedt, 1991), but this identification scheme was not widely used by other research groups.

Chemotaxonomic and molecular methods were used in parallel with the application of numerical taxonomic procedures for the classification of streptomycetes. The additional phenotypic methods used to study streptomycetes included cell-wall analysis (Lechevalier and Lechevalier, 1970a, 1970b, 1970c), fatty acid profiling (Hofheinz and Grisebach, 1965; Kroppenstedt, 1992; Lechevalier, 1977; Saddler et al., 1986, 1987), rapid biochemical tests based on the use of 4-methyl-umbelliferone-linked substrates (Goodfellow et al., 1987b), serological assays (Ridell et al., 1986), phage typing (Korn-Wendisch and Schneider, 1992; Wellington and Williams, 1981b), Curie-point pyrolysis MS of whole cells (Ferguson et al., 1997; Sanglier et al., 1992), whole organism protein profiling (Goodfellow and O'Donnell, 1993; Lanoot et al., 2002; Manchester et al.,

1990), and comparison of ribosomal protein patterns (Ochi, 1989, 1992, 1995).

Fatty acids. Hofheinz and Grisebach (1965) examined selected *Saccharopolyspora erythraeus* (formerly "*Streptomyces erythraeus*") and *Streptomyces halstedii* strains to clarify the biosynthetic pathway of branched-chain fatty acid synthesis. They found that *Streptomyces* strains synthesized terminally branched fatty acids; the starting compound, 2-methylbutyrate, led to the synthesis of anteiso-branched fatty acids with an odd number of carbon atoms. In contrast, isovalerate and isobutyrate were the starting compounds that lead to the formation of iso-branched fatty acids with even and odd numbers of carbon atoms, respectively. Consequently, iso- and anteiso-branched fatty acids appear in pairs with odd numbers of carbon atoms.

Hofheinz and Grisebach also identified individual fatty acids by first separating them as their methyl esters by GC on different stationary phases, then analyzing the results by comparing the equivalent chain-lengths of unknown fatty acids with those of standard mixtures. Preparative GC and physical methods, such as MS and NMR spectrometry, confirmed these results. Iso- and anteiso-branched fatty acids with chain lengths of 15 and 17 carbon atoms were detected in both *Saccharopolyspora erythraeus* and *Streptomyces halstedii*. In addition, high amounts of 14-methylpentadecanoic acid ($C_{16:0}$ iso) were found, whereas minor amounts of unbranched fatty acids, tuberculostearic acid and their homologs were detected in the *Saccharopolyspora erythraea* strains, but not in *Streptomyces halstedii*.

A limited number of streptomycetes synthesize small amounts of hydroxy fatty acids in the presence of optimal amounts of oxygen. These fatty acids are easily destroyed in a non-deactivated injection port of capillary GC systems. Hence, they are not always detected. However, some streptomycetes produce hydroxy fatty acids which are highly diagnostic when strains are grown under reproducible culture conditions. Hydroxy fatty acids have been detected in all strains of *Streptomyces coelicolor* (30), in 20 of 27 *Streptomyces hygroscopicus* strains, *Streptomyces rimosus* (14), and *Streptomyces violaceusniger* (18), but not in *Streptomyces albus* (33), *Streptomyces fradiae* (25), *Streptomyces glaucescens* (8), *Streptomyces griseus* (22), *Streptomyces lavendulae* (18), *Streptomyces violaceoruber* (16), or *Streptomyces viridochromogenes* (25; Kroppenstedt, 1992; R.M. Kroppenstedt, unpublished observations).

Standardized growth and cultivation conditions are prerequisites for generating fatty acid patterns for classification below the genus level (Saddler et al., 1986). These workers examined the fatty acid profiles of *Streptomyces cyaneus* strains and associated soil isolates, which produced a blue aerial spore mass; 13 of 19 blue-spored strains belonged to the *Streptomyces cyaneus* cluster (Hütter, 1962; Korn et al., 1978; Pridham and Tresner, 1974a). Saddler et al. (1987) showed that 8 of 10 blue-spored isolates were grouped together based on fatty acid data, whereas 17 of 34 *Streptomyces cyaneus* strains were assigned to a separate cluster. Saddler and his colleagues concluded that conventional features, like spore chain morphology, color, and ornamentation of spores, were not reliable for the classification of streptomycetes, but would be helpful for presumptive identification, a point also made by Williams et al. (1983a). However, Saddler and his colleagues demonstrated that the *Streptomyces cyaneus* taxon as defined by Williams et al. (1983a) was heterogeneous.

In general, fatty acid patterns cannot be used to delimit *Streptomyces* species (Phillips, 1992; R.M. Kroppenstedt, unpublished observation), but are still useful for the rapid characterization (independent of the taxonomic status) of large numbers of wild-type streptomycetes isolated from the environment when used under standardized conditions (Saddler et al., 1987). Identification and quantification can be done by using the automated commercially available MIDI system consisting of a Hewlett Packard model 5890 capillary GC and a computer with specific software (Microbial ID, Inc., Newark, DE). The MIDI system automatically identifies fatty acids using fatty acid standard mixtures for comparison. However, comparisons of different analytical methods show that numerical methods cannot be used for classification, because different methods give different groupings. Additionally, the resolution is not good; hence, too many strains are grouped together into some clusters (Kämpfer et al., 1991; Williams et al., 1983a).

Curie-point pyrolysis MS. Another method that has been applied to the classification and identification of actinomycetes is pyrolysis MS (PyMS; Sanglier et al., 1992; Ferguson et al., 1997). Whole cells exposed to high temperatures are degraded in a nonoxidative environment leading to the generation of pyrolysate, which can be analyzed by MS. This method needs to be rigorously standardized and results in the production of a fingerprint for each organism.

Sanglier et al. (1992) applied this method to strains belonging to the *Streptomyces albidoflavus* species-group defined by Williams et al. (1983a) and recovered *Streptomyces albidoflavus* and *Streptomyces anulatus* strains in distinct groups. The six *Streptomyces halstedii* strains (the third subgroup) were assigned to three groups. *Streptomyces albidoflavus* and *Streptomyces anulatus* strains were also recovered in different groups by Kämpfer et al. (1991). They also found that *Streptomyces anulatus* ISP 5361^T, the strain used to name the *Streptomyces anulatus* cluster, formed a single-membered cluster (Kämpfer et al., 1991).

Serology. Serological methods have rarely been used in *Streptomyces* systematics. Ridell et al. (1986) used antisera against the mycelia of streptomycetes, streptoverticillia, and *Nocardiopsis* species to confirm the high similarity between *Streptomyces lavendulae* and streptoverticillia (Kämpfer et al., 1991; Witt and Stackebrandt, 1990). The antisera of Kirby and Rybick (1986) were shown to be genus-specific and to a certain degree also group-specific when tested against *Streptomyces griseus* (*Streptomyces anulatus*, cluster 1B of Williams et al., 1983a) and "*Streptomyces cattleya*" (cluster 47 of Williams et al., 1983a). Wipat et al. (1994) generated a monoclonal antibody to "*Streptomyces lividans*" 1326 which was specific for "*Streptomyces lividans*" strain 1326 and for strains assigned to cluster 21 by Williams et al. (1983a).

Phage typing. Phage typing can be used for host identification at the genus and species levels (Korn et al., 1978; Kutzner, 1961a, 1961b; Wellington and Williams, 1981b; Welsch et al., 1957). Many actinophages, mainly virulent, have been used for phage typing. Two different groups of streptomycete phages exist, namely polyvalent phages (e.g. φC31; Chater et al., 1986) and species-specific phages (Anderson and Wellington, 2001; Table 271). Actinophages are specific at the genus level (e.g. Wellington and Williams, 1981b; Korn-Wendisch, 1982;

TABLE 271. Species-specific actinophages of the genus *Streptomyces* (modified according to Anderson and Wellington, 2001)

[b]Clusters according to Kämpfer et al. (1991).

Prauser, 1984). Actinophage host range studies helped to justify the transfer of the genera *Actinopycnidium*, *Actinosporangium*, *Chainia*, *Elytrosporangium*, *Microellobosporia*, *Kitasatoa*, and *Streptoverticillium* to the genus *Streptomyces* (Goodfellow et al., 1986a, 1986c, 1986d, 1986e; Witt and Stackebrandt, 1990). Similar studies supported the transfer of *Actinoplanes armeniacus* to the genus *Streptomyces* (Kroppenstedt et al., 1981; Wellington and Williams, 1981a) and "*Streptomyces erythraeus*" to the genus *Saccharopolyspora* (Labeda, 1987). Phage typing has been shown to be less useful for species or group identification of *Streptomyces*, though there are a few exceptions (Table 271).

Phages are widely used in industrial microbiology (Carvajal, 1953; Ogata, 1980) and in genetic studies (see Chater, 1986), as exemplified in chapter 12 of Kieser et al. (2000). The temperate phage, φC31, is one of the best-investigated temperate actinophages and has a broad host range within the genus *Streptomyces* (Lomovskaya et al., 1980). This phage has been employed for many purposes (e.g. transfection, transduction, detection of transposon-like elements of host DNA, and cloning); details can be found in chapter 12 of Kieser et al. (2000).

Protein profiling. PAGE is used to analyze total protein extracts resulting in more or less complex banding patterns. These patterns have been used to clarify relationships between the species and subspecies levels of various bacterial genera. One-dimensional (1-D) and two-dimensional (2-D) protein electrophoresis can be used to determine protein patterns. Manchester et al. (1990) used one-dimensional protein electrophoresis to examine 37 *Streptomyces* strains, including five streptoverticillia, and found some taxonomic correlations between the resultant profiles and groups based on phenotypes (Kämpfer et al., 1991; Williams et al., 1983a) and DNA hybridization data (Table 272). However, only a few of these correlations were confirmed by Lanoot et al. (2002).

PAGE and DNA–DNA hybridizations were used to elucidate the taxonomy of *Streptomyces* isolates that caused common potato scab (Paradis et al., 1994). The isolates were the subject of an SDS-PAGE analysis and found to belong to two groups with a correlation coefficient of 0.75. The same groups were recovered in the DNA–DNA relatedness study, though not in the corresponding fatty acid analysis. This lack of correlation can be attributed to the influence of growth conditions on fatty acid profiles (Saddler et al., 1986, 1987). The protein profiling did not allow pathogenic and nonpathogenic strains to be differentiated. Lanoot et al. (2002) used SDS-PAGE of whole-cell proteins in an examination of 93 *Streptomyces* reference strains. Subsequent computer-assisted numerical analysis revealed 24 clusters, which included strains with very similar protein profiles. Several type strains were assigned to five clusters, which had visually identical patterns. DNA–DNA hybridizations of these type strains revealed similarities higher than 70%. On the basis of these results, *Streptomyces albosporeus* subsp. *albosporeus* LMG 19403[T] was considered to be a subjective synonym of *Streptomyces aurantiacus* LMG 19358[T], *Streptomyces aminophilus* LMG 19319[T] was a subjective synonym of *Streptomyces cacaoi* subsp. *cacaoi* LMG 19320[T], *Streptomyces niveus* LMG 19395[T] and *Streptomyces spheroides* LMG 19392[T] were subjective synonyms of *Streptomyces caeruleus* LMG 19399[T], and *Streptomyces violatus* LMG 19397[T] was a subjective synonym of *Streptomyces violaceus* LMG 19360[T] (Table 272).

Two-dimensional PAGE of the total cellular proteins gives greater resolution than one-dimensional studies. Very complex patterns can be obtained with 2-D PAGE, though this method seems to be too sensitive to differentiate between proteins with high rates of evolution (Hori and Osawa, 1987). Two-dimensional PAGE studies designed to distinguish between ribosomal proteins of streptomycetes were first described by Mikulik et al. (1982) and later by Ochi (1989). Subsequently, AT-L30 proteins were found to give genus-specific profiles (Ochi, 1992), while analyses of the N-terminal sequences of the ribosomal AT-L30 protein allowed streptomycete strains to be assigned to different taxonomic groups (Ochi, 1995); these groups were assigned to phylogenetic groupings which suggested that the genus *Streptomyces* was well described. However, no correlation was found between Ochi's groupings and numerical phenetic groups (Kämpfer et al., 1991; Williams et al., 1983a). Details of these groupings are in Table 272.

Multilocus enzyme electrophoresis (MLEE) results in more specific patterns than protein profiling. MLEE depends on the relative mobilities of cellular enzymes in a gel matrix. In a small study of 24 *Streptomyces* strains (Oh et al., 1996), both inter- and intraspecific characterization of the organisms was achieved, if the appropriate enzymes were used.

The isolation and sequencing of specific proteins led to more detailed taxonomic studies of some *Streptomyces*. The *Streptomyces* subtilisin inhibitor protein (SSI), for example, was used by Taguchi et al. (1996) to determine the taxonomic status of "*Streptomyces lividans*" 66, *Streptomyces coelicolor* Müller ISP 5233^{T}, and *Streptomyces coelicolor* A3(2); this protein plays unidentified role(s) in physiological or morphological regulation. Ribosomal sequence comparisons were supported by the alignments of the SSI indicating that *Streptomyces coelicolor* A3(2) is more closely related to "*Streptomyces lividans*" 66 [cluster 21 of Williams et al. (1983a)] than to the type strain, *Streptomyces coelicolor* Müller ISP 5233^{T} (cluster 1).

Genotypic methods. Genotypic methods encompass all procedures that are directed towards DNA and RNA molecules (Schleifer and Stackebrandt, 1983; Vandamme et al., 1996). The analysis of bacterial genomes by molecular methods has provided a new basis for studying bacterial taxonomy. In some cases, phylogenetic relationships of prokaryotes could be studied at the genus, species, and even subspecies level, leading to a wide use of these methods in modern taxonomic studies. Vandamme et al. (1996) described the general taxonomic values of different molecular techniques, while Anderson and Wellington (2001) considered their use in streptomycete systematics. In the following, the usefulness of these methods in the delineation of species within the genus *Streptomyces* is discussed briefly.

By comparative analysis of sequences of homologous and genetically stable semantides, it was shown that several classification systems based on morphology and physiology did not reflect the natural relationships among actinomycetes and related organisms (Stackebrandt and Schumann, 2006). In this respect, sequence analysis of the rRNA gene has revolutionized our insight into phylogenetic lineages of major taxonomic groups. Nevertheless, 16S rRNA gene sequencing does not always have the resolving power to delimit species. Additionally, while new strains should not be assigned to existing species solely on the basis of this molecule, rRNA gene sequence comparisons do play an important role in the taxonomy of *Streptomyces* and in studying horizontal gene transfer within the genus (Huddleston et al., 1997).

Three regions within 16S rRNA genes have been found to show enough variability to be useful as genus-specific (*a* and *b* regions) and species-specific (*c* regions) probes [see Stackebrandt et al. (1991a, 1991b, 1992) and Anderson and Wellington (2001)]. Next to 16S rRNA genes, 23S rRNA and 5S rRNA genes (Mehling et al., 1995), 16S–23S rRNA internally transcribed spacer (ITS) sequences (Song et al., 2003), and ribosomal protein sequences have been used to investigate relationships between *Streptomyces* (Liao and Dennis, 1994; Ochi, 1995). The ITS sequences of the six rDNA operons from two *Streptomyces ambofaciens* strains were analyzed by Wenner et al. (2002), who confirmed that a high degree of ITS variability was a common characteristic amongst *Streptomyces* species. They also showed that recombination frequently occurs between rDNA loci leading to the exchange of nucleotide blocks. Given such intraspecific variation and intragenomic heterogeneity rRNA gene sequences cannot solely be used for taxonomic studies.

DNA hybridization. The DNA–DNA hybridization values (%) and the decrease in thermal stability of hybrids are currently used as the "gold standards" for species delineation in bacteriology (Wayne et al., 1987), despite the recommendations of the Ad hoc committee for the re-evaluation of the species definition in light of the application of other methods (Stackebrandt et al., 2002), DNA–DNA similarity and changes in melting temperature (ΔT_m; Wayne et al., 1987) still remain the acknowledged standards for the definition of species.

DNA–DNA hybridizations of total chromosomal DNA have been widely used in the classification of *Streptomyces* species. In an initial study, strains of the *Streptomyces albidoflavus* cluster 1, defined by Williams et al. (1983a) using numerical phenetic methods, were the subject of DNA–DNA hybridization studies, performed by reassociation of labeled DNA on nitrocellulose filters (Mordarski et al., 1986). Good congruence was found between the results of the two approaches and the homogeneity of the *Streptomyces albidoflavus* subcluster *albidoflavus* was confirmed. However, two further subclusters obtained by DNA–DNA hybridization were not congruent with the *Streptomyces anulatus* or *Streptomyces halstedii* subclusters of Williams et al. (1983a), though some correlation was found with the groupings of Kämpfer et al. (1991). DNA–DNA pairing data supported the assignment of *Streptoverticillium* strains to the genus *Streptomyces* (reassociation of labeled DNA on filters; Witt and Stackebrandt, 1990), a result that was confirmed in the numerical phenetic study of Kämpfer et al. (1991).

The most extensive DNA–DNA hybridization (thermal renaturation method) studies on strains assigned to some of the major phenetic groups of Williams et al. (1983a) were carried out by Labeda and his colleagues (Labeda, 1993, 1996, 1998; Labeda and Lyons, 1991a, 1991b). They found little correlation between the DNA–DNA pairing and numerical phenetic data with respect to the *Streptomyces cyaneus* (Labeda and Lyons, 1991a), *Streptomyces violaceusniger* (Labeda and Lyons, 1991b), *Streptomyces lavendulae* (Labeda, 1993), the verticil-forming streptomycetes (formerly *Streptoverticillium* species; Labeda, 1996; Hatano et al., 2003), and *Streptomyces fulvissimus* and *Streptomyces griseoviridis* phenotypic clusters (Labeda, 1998), though some correlation was found with phenotypic groups circumscribed by Kämpfer et al. (1991) (Table 272). The fact that certain regions within the *Streptomyces* chromosome show considerable genetic instability supports the continued use of DNA–DNA pairing (Redenbach et al., 1993). However, DNA–DNA hybridization data can be influenced by the presence of large plasmids in *Streptomyces* strains. The general properties of *Streptomyces* plasmids and their use for gene cloning are considered in chapter 11 of Kieser et al. (2000).

TABLE 272. List of *Streptomyces* species (including *Kitasatospora* and *Streptacidiphilus* species) arranged according to the grouping given in Figure 339
